An Address

ON
RENAL TUBERCULOSIS.

Being the Presidential Address to the Section of Urology of the Royal Society of Medicine on Oct. 30th, 1924.

By CYRIL A. R. NITCH, M.S. LOND.,
F.R.C.S. ENG.,

SURGEON TO ST. THOMAS'S HOSPITAL, ETC.

(WITH COLOURED PLATE.)

I HAVE selected the subject of renal tuberculosis because it has not yet been brought before the Section and because I have complete post-operative details of a number of cases. As limitations of time will not permit of a complete review, I have only selected certain aspects of the disease, some of which are open to differences of opinion, and I shall refrain from giving more than a brief summary of the cases I have investigated.

Judging from hospital records the disease is not nearly so common in this country as on the continent, for in the last 12 years only 47 cases of surgical tuberculosis of the kidney appear to have been admitted to St. Thomas's. This probably does not represent a true total, for doubtless during the war years a certain number of cases escaped the Registrar, and probably several with primary renal tuberculosis were admitted to the medical and gynaecological wards and both treated and recorded as tuberculous cystitis. Fortunately, owing to the work of urologists in this country, physicians and gynaecologists are becoming more enlightened, and within recent years have sought the aid of their surgical colleagues for cases of "cystitis" instead of treating them with urinary antiseptics and tuberculin.

CLINICAL VARIETIES.

Renal tuberculosis is a disease of unusual interest because of the two distinct clinical varieties which we call medical and surgical respectively.

In the medical form the disease is bilateral, infection is nearly always hæmic, there is a coexistent parenchymatous nephritis, the urine is clear but contains tubercle bacilli, albumin of sanguineous origin, and hyaline and granular casts. Physical signs of chronic nephritis in the form of oedema with arterial and cardiac changes are often present and death from uræmia is not uncommon. The actual tubercles are scattered irregularly throughout the cortex and medulla, the greatest number being in the cortex, but as Bedo Hobbs has pointed out, though tubercles are often limited to the cortex they are seldom found in the medulla without a cortical lesion.

In the surgical form the disease is unilateral at the commencement, infection takes place by the blood- or lymph-streams, the urine is cloudy or turbid, and contains tubercle bacilli, pus cells, caseous material, fragments of renal tissue, phosphates, red blood corpuscles, and albumin of pyogenic origin. The focal lesions are limited in number and undergo caseation and liquefaction, forming an open or closed tuberculous abscess. The pathological anatomy is similar in its essentials to that of the medical form, but differs in degree, and will be discussed more fully later on.

It is curious that two types should exist with such wide clinical differences, the one with multiple tubercles and albuminuria, and the other with a limited number of tubercles and pyuria. I am inclined to think that the difference is only one of degree. In the medical form, the resistance of the kidney is lowered by a toxic inflammation which accounts for the albumin in the urine, and by frequent assaults by myriads of bacilli which are suddenly liberated from the primary focus—e.g., the lung. Eventually the day comes when the kidney, with lowered vitality and with its arterioles the seat of a chronic endarteritis, no longer

excretes all the bacilli and multiple tubercles develop. That they do not undergo caseation and liquefaction is due to the fact that death cuts the process short. In the surgical variety the tubercles form only after attacks by a small number of bacilli at considerable intervals, aided by a local rather than a total lowered resistance. These tubercles remain dormant for months or years and eventually undergo caseation and liquefaction, changes typical of a chronic infection. This view is strengthened by Macfarlane Walker's interesting observation that early albuminuria is a precursor of genital tuberculosis. In two of his patients albuminuria preceded the tuberculous lesions by five years and pointed to the urine as the infecting agent.

CHRONIC OR SURGICAL RENAL TUBERCULOSIS.

Having briefly considered these two main types, I shall confine my remarks to the chronic or surgical form of renal tuberculosis. The interest that has centred on the disease is shown by its voluminous literature; in fact, Randall, an American surgeon, writing in 1919, found that no less than 1500 articles had been published in the preceding ten years, and yet the post-operative cures only average 60 per cent. In view of the good results of the surgical treatment of tubercle in other parts of the body, provided the whole infective focus can be removed, and of the fact that renal tuberculosis is, in its early stage, limited to the substance of an organ surrounded by a good fibrous capsule; it is evident that we have yet to discover a method of diagnosing the disease in its early, or what I prefer to term, its operable stage.

It is now well known that the disease is primarily unilateral, and that the only hope of cure lies in an early nephrectomy. Spontaneous cure is extremely rare, and only a few authentic cases have been published in which the disease in the kidney appears to have been arrested, and in which the death of the patient was due to an entirely different cause. Albarran collected five cases from the literature, Rafin reported four, which, however, were not verified by post-mortem examinations, and Randall has published one case of closed tuberculosis in which death was due to pernicious anæmia, but even in this sceptics might argue that the blood changes were due to the renal lesion. More recently Bedo Hobbs, in a study of fatal cases of pulmonary tuberculosis, found fibrous nodules in the kidneys which resembled the scars of healed tubercles. Wildbolz and others have reported cases with a tuberculous kidney who have lived from 10 to 30 years in fair health. These are rare instances of autonephrectomy in which occlusion of the ureter and pelvis is followed by total caseation and necrosis, but they are so rare as to be negligible.

Bilateral, surgical tuberculosis is practically always secondary to a primary unilateral infection, which, if allowed to persist for a sufficient length of time, will spread to the lower urinary tract and slowly but surely reach the opposite and once healthy kidney. Continental writers (Israel, Caspar, Albarran, and Legueu) have estimated from an enormous number of cases that bilateral surgical infections should not exceed 15 per cent., but more recently Braasch has shown by animal inoculation that in seven out of 22 cases apparently unilateral the opposite side was infected, and further that after removal of the obviously diseased kidney all these patients have signs of active urinary tuberculosis. These results indicate that our conception of an apparently unilateral lesion may require reconsideration.

In the post-mortem room the figures for bilateral infection are very different, being placed by Kummel and Kapsamer at 64 per cent. and 68 per cent. respectively. Ekehorn has endeavoured to deal with this problem by exposing both kidneys and removing the more diseased one when he considered it to be the cause of pyrexia and distressing bladder symptoms. In 20 cases so treated between 1910 and 1922 the immediate result was a pronounced diminution in the pain and pyuria. Subsequently ten died,

five could not be traced, and five were still alive. Two of the survivors were free from pain and able to work 12 years after the operation, their only symptoms being nocturnal frequency; and a third was in a similar condition five years after the operation. Two of the fatal cases had lived six years and two years. Though this method of treatment is not applicable to every case, it is certainly justifiable in some, if by its means the distressing symptoms of a heavily infected bladder can be alleviated. In the Mayo Clinic the results were not so satisfactory, for out of 18 cases so treated four died immediately after the operation and ten within 18 months, either from renal insufficiency or tuberculous foci in other parts of the body.

SEX AND AGE.

In my series of 65 cases there were twice as many females as males, but this is unusual, for the majority of figures show that the two sexes are affected equally. The commonest age is from 20 to 30. No less than 84 per cent. of my cases were between 20 and 50, figures which curiously enough are precisely similar to those quoted by Judd and Scholl in a series of 874 cases. The right kidney is affected rather more often than the left, and in my cases the percentages were 52 and 46 respectively. It is suggested that this is due to the greater mobility and lower position of the right kidney, which favours congestion and exposes it to injury, but the difference is so slight that there is no need to waste time in conjecture.

PATHS OF INFECTION.

In the past there have been considerable differences of opinion in regard to the route by which tubercle bacilli reached the kidney, but now there are only two channels which need be considered—the blood-vessels and the lymphatics. The ureteric route, for reasons which will be given, can be disregarded. A careful study of the pathological anatomy of the disease makes it clear that a primary infection nearly always takes place through the blood-stream. It is hardly necessary to point out that the term "primary infection" is not scientifically correct, for the bacilli must have originated in some tuberculous focus, most probably a tuberculous mediastinal gland, but it signifies that the kidney has been infected from a quiescent and obscure lesion.

The Hæmatogenous Route.

It is difficult to specify the exact site of the initial lesion in the kidney, for an operation specimen is seldom obtained at an early enough stage of the disease, and when several foci are present it is almost impossible to determine their relative age. In all probability the anatomical arrangement of the intra-renal blood-vessels plays an important part. Briefly it is as follows: The branches of the renal artery pass between the pyramids and form a series of incomplete arches across their bases. These are practically end arteries, for there is no anastomosis between adjacent arches. From these arches two sets of branches arise; one set, termed interlobular, passes straight to the cortex, and the other, the arteriolar rectæ, takes a recurrent course and supplies the base of the pyramids and the intermediate zone of the medulla. In the labyrinth each interlobular artery gives off a number of vessels which form glomeruli at the dilated extremities of the uriniferous tubules. Injected kidneys, both of man and the dog, show clearly the arterial arches giving off an enormous number of branches to the cortex, and so few to the papillæ as to make them appear almost avascular. As an interlobular artery is practically a continuation of the interlobar vessel, and is also larger than the recurrent arteriolar rectæ, tubercle bacilli in the blood-stream are most likely to be carried along them, either to lodge in the cortex, where they give rise to a tuberculous nodule, or to enter a glomerulus and escape into a uriniferous tubule. Here they may either lodge in a convoluted tube and thus form a primary cortical lesion, or they may be swept away in the urine. An excellent argu-

ment in favour of the earliest lesions being in the cortex is given by Bedo Hobbs in his paper in *Tubercle*, to which those interested in the subject are referred. He also states that Walsh, in a careful study of 52 cases, found the cortex affected alone in 26, both cortex and pyramids in 24, and the pyramids alone in two; and that Hallé in his writings on closed parenchymatous nephritis agrees that tuberculous foci appear most frequently in the cortex, next at the junction of the cortex and medulla at the level of the vascular arches, and least frequently in the pyramid. Many clinicians consider that the primary focus is located in the base of a pyramid, as this is the site of the grossest lesions in the majority of operation specimens. This, in my opinion, does not in any way negative the theory of a primary cortical origin, for in view of the fact that the intra-renal lymph-stream flows from the cortex to the medulla, bacilli from an initial small tubercle in the cortex can be carried by the lymph to the pyramids, which, as I have already pointed out, have a very poor blood-supply. Consequently, arrest of the organisms in this anæmic area is followed by extensive necrosis and the formation of a large tuberculous focus which overshadows the small primary lesion in the cortex.

The Lymphatic Route.

In a certain proportion of cases the primary infection of the kidney takes place through the lymphatics. This is made possible by the free communication between the various lymphatic systems in relation with it. Three plexuses are described: one in the kidney substance, a second beneath the fibrous capsule, and a third in the perinephric fat. Vessels from the intra-renal plexus converge to form four or five trunks, which emerge at the hilum, where they are joined by vessels which emerge from the subcapsular and perinephric plexuses. The subcapsular plexus communicates freely with the plexus in the perinephric fat, and also with the intra-renal plexus by trunks which enter the cortex in relation with the fibrous septa of the kidney. Free communication also exists between the renal and subdiaphragmatic lymphatics above, and those of the upper ureter below. The three sets of ureteric lymphatics form a more or less continuous chain, and the lowest communicate freely with those of the bladder, prostate, uterus, and Fallopian tubes. This free communication has been proved both experimentally and clinically by many observers, amongst whom I may mention Mr. Kenneth Walker (*THE LANCET*, 1922, i., 684). In the discussion which followed his paper, I mentioned several cases which had come under my notice of acute prostatic abscess followed by perinephric abscess, clinical evidence which clearly demonstrates the intimate connexion between the pelvic and perirenal lymphatics. As is well-known, Brongersma is a strong advocate of this mode of infection, and considers that in many cases the bacilli reach the kidney from the lung or pleura via the lymphatics through the diaphragm. Franke holds similar views. It has also been suggested that the communication between the colic and renal lymphatics constitutes another method of infection. At present, however, there is not sufficient evidence to allow of any definite conclusions that primary renal tuberculosis is often caused through the lymphatics. In secondary infections (i.e., infection of a healthy kidney from a long-established focus on the opposite side), which are not hæmic in origin, the lymphatics play a very definite part. In these instances bacilli from the diseased kidney travel in the urine to the bladder, where they gain access to the tissues through an abrasion or ulcer, and are then carried upwards to the healthy kidney in the peri-ureteral lymphatics. Walker considered this to be the interpretation of the post-mortem findings in one of his cases which died of advanced tuberculosis of the left kidney, bladder, and prostate. The inner coat of the left ureter was the site of extensive tuberculous infiltration, but on the right side the peri-ureteral tissues were infiltrated and the inner coat of the ureter was healthy.

Ureteric Route.

As a result of experimental work by George Walker, Baureisen, Draper and Braasch, and recently by Dyke and Maybury, it has been proved conclusively that micro-organisms cannot pass directly up the ureter from the bladder to the kidney. The last-named (Dyke and Maybury) endeavoured to infect the kidneys of the rabbit by placing in the bladder a piece of Turkey sponge saturated with a thick emulsion of *Staphylococcus aureus*. The uniformly negative results led them to conclude "that the uretero-vesical junction offered, under the experimental conditions, an insuperable bar to the passage of infection from the bladder upwards." Another series of experiments "performed with a view to bring about the passage of cocci, or carmine granules, or Indian ink, from the pelvis into the renal tubules" was also fruitless and led to the conclusion that the renal papilla acted as a valve, and rendered infection of the renal tubules in the reverse direction quite impossible. When the epithelium, lining the renal sinus, was damaged there was a direct infection in the adjacent renal tissue and beneath the capsule. Therefore it is fair to conclude that direct spread of infection up the lumen of a sound ureter has not yet been proved. If its epithelium is damaged by trauma or inflammation, an ascending infection is possible, but it then takes place by direct extension in the walls of the ureter or in its lymphatics.

PATHOLOGY.

The best account is given by Hallé, who describes three types of chronic renal tuberculosis. (1) Primary closed parenchymatous tuberculous nephritis. (2) Primary open tuberculous pyelitis or pyelonephritis. (3) A combination of (1) and (2).

Alexander Randall has summarised these so clearly* that I cannot do better than quote him verbatim:—

"In the first, the primary closed parenchymatous tuberculous nephritis, the infection is situated in the parenchyma, most frequently in the cortex; it is limited and easily encapsulated; the peripherally growing lesions progressively involve the poles and lobules, forming cold abscesses, and end by a closed cavernous parenchymatous tuberculosis, with one or two ultimate conclusions—liquefaction or caseation. The lesions may be multiple, and as the condition progresses and the entire kidney becomes involved, secretion ceases. Interstitial pelvic inflammation ultimately destroys this portion of the organ, and its area is replaced by a fibro-lipomatous degeneration and scar tissue. The condition ends by 'total, successive, or simultaneous exclusion of the kidney,' or 'spontaneous nephrectomy.' Time simply adds atrophy to the process."

The term "closed" implies that the products of disintegration are not being emptied into the bladder. This is due to obliteration of the ureter and simultaneous or subsequent destruction of the kidney. Fig. I. on Coloured Plate illustrates these points and conforms to an early stage of this type. The tubercles are limited to the two poles and at the upper pole an eroded papilla is visible. The lower pole contains tubercles, caseous deposits, and abscess cavities; fibro-lipomatous degeneration is seen in the middle. The pelvis is healthy except in an upper calyx. The ureter was obliterated at the back of the bladder by a large caseous focus. The ureteric orifice, Fig. II., was hidden in a mass of bullous oedema resembling a mulberry in size and shape.

The kidney was removed from a woman, aged 37, with frequency and pyuria of four months' standing. When seen the urine contained pus and was sterile; repeated examinations for tubercle bacilli were negative. There was no efflux from the left ureter, nor was any indigo-carmin to be seen half an hour after injection. A mild cystitis accounted for the pyuria. Per vaginam a slightly thickened ureter could be felt. Three months after nephro-ureterectomy the patient was perfectly well, the ureteric orifice and the bladder were normal in appearance, and the urine was clear and free from tubercle bacilli.

In the second type, primary open tuberculous pyelonephritis, "the infection originates in the tissues of the renal pelvis high in the calyces and the papillo-

calicular sinuses. It occasions a progressive ulceration, working up into the renal tissue from the lateral surfaces of the papillae. Deeper lesions may develop, but the calicular lesions are always the more advanced, and the infection remains essentially a tuberculous pyonephrosis" (Randall). The pathologic products of the diseased kidney escape into the bladder, and in this type frequently give rise to a "golf-hole" ureteric orifice and ulceration of the adjacent mucosa. Fig. III. is a fair illustration of the type, showing advanced calicular and pelvic ulceration with destruction of the papillae. In the cortex are two cavities which contained caseous material, and were probably the initial lesions in this case. In the upper pole several tubercles are visible, arranged in rows as if formed in a lymphatic duct. The ureteric orifice (Fig. IV.) is open, dragged out, and surmounted by a large tuberculous ulcer.

The kidney was removed in January, 1913, from a female aged 48, with a year's history of chronic cystitis and occasional hæmaturia. Six years after the operation she was in good

FIG. V.

Mixed variety. A combination of Types I. and II.

health and weighed 12 st. She still had frequency about two-hourly day and night. Her urine contained pus, bacteria, and a trace of blood. No tubercle bacilli were found.

The third type is a mixed one where both of the above processes are coexistent. Fig. V. is a good specimen of the variety showing in its lower half closed parenchymatous nephritis which has progressed to caseation and almost complete destruction of the renal tissue, and in its upper half papillo-calicular ulceration and numerous tubercles, which are arranged in rows in several places.

The specimen was obtained in 1912 from a female aged 37, who had suffered from frequency and occasional hæmaturia for three years. Tubercle bacilli were found in the urine a year after the commencement of bladder symptoms. She was treated with tuberculin and improved for a time, but relapsed again when it was discontinued. The ureteric orifice was drawn out and the surrounding mucosa was congested and oedematous, and contained two tubercles. Nephrectomy with high division of ureter. The latter was thickened but its mucous membrane appeared healthy. In June of this year—i.e., 12 years after the operation—she was reported to be in good health, but I was not able to obtain further details.

* Journal of Urology, vol. ii., No. 6, p. 429.

Hallé's figures show that the mixed type is the commonest clinically, and that types I. and II. are of about equal occurrence post mortem. It will be noticed that Hallé considers that the second type is papillary in origin, but this view is open to argument, for there is no proof that the initial focus is not a small one in the cortex, and that the papillary lesion is a natural sequence of intra-renal lymphatic extension analogous to the minute but infected tonsillar crypt, which only attracts attention through the enlarged cervical gland. As I have already shown, the comparative avascularity of the papillæ encourages the development of a tuberculous focus, and as soon as its epithelial covering is destroyed contamination by the urine in the pelvis accelerates its spread.

DIAGNOSIS.

The diagnosis depends on the symptoms of vesical irritation combined with an acid, turbid, sterile urine containing pus cells, tubercle bacilli, and occasionally

FIG. VI.

Showing kidney (A) still attached to ureter and line of incision (B) for exposure of pelvic portion of ureter.

blood in varying amounts. Given these data the site of the lesion is determined by cystoscopy. There are many interesting points in connexion with the diagnosis which I might refer to, but I do not propose to inflict them on you now, and will only discuss the presence or absence of tubercle bacilli in the urine. In the closed form just described tubercle bacilli cannot enter the bladder, and are therefore often absent from the urine. When present they must originate in some portion of the urinary tract below the obstructed ureter. The diagnosis of chronic renal tuberculosis can then only be made by the appearance of the ureteric orifice, the absence of efflux, and by the thickened ureter which can readily be felt bimanually, and is a positive indication of the renal lesion. In a typical case of open renal tuberculosis tubercle bacilli are found in an acid purulent urine, and there is no difficulty either in making the diagnosis or deciding on the correct treatment, but when bacilli are found in a clear urine the question arises whether tubercle bacilli can percolate through the kidney without injuring its substance. The published figures of several observers show that tubercle bacilli are excreted in a clear urine in about 9 per cent. of patients with pulmonary tuberculosis,

and post-mortem examinations have shown that tuberculous foci are present in the kidneys of some and absent in others. But can a kidney excrete, for a prolonged period, a normal urine containing large numbers of tubercle bacilli originating from an obscure and undiscoverable focus without itself being damaged, and if, in such a case, the physical signs incriminate one kidney, should surgical treatment be withheld? The answer is Yes, as the following case proves:—

In 1913 I removed a gangrenous appendix from a girl of 9 years who was otherwise healthy. Six days later she had a sudden attack of acute pain in the left kidney followed by profuse hæmaturia. The urine, examined by Prof. L. S. Dudgeon, contained blood cells only and cultures were sterile. The kidney was tender, and there was slight pyrexia, but otherwise there were no physical signs. The hæmorrhage diminished gradually and on the fifth day Prof. Dudgeon reported that the urine was still sterile, but that it contained more leucocytes than were compatible with normal blood, and that their presence suggested an inflammatory lesion of the kidney. Fifteen days after the onset of hæmaturia a perfectly clear and apparently normal specimen of urine was found to be swarming with tubercle bacilli, which were proved by animal inoculation. The excretion of bacilli continued for two and a half months and then ceased. The patient has been perfectly well ever since, and is now a well-developed girl over 20 years old.

Now, this is either a clear case of a leaking kidney or of one containing numerous parenchymatous tubercles, which, after pouring myriads of bacilli into the glomeruli and tubules, eventually healed completely, a possibility which most authorities emphatically deny. In fact, J. R. Caulk states that "there has never been in the history of medical literature a single authentic case of spontaneous healing of a tuberculous kidney."

TREATMENT.

The treatment of unilateral renal tuberculosis can be summed up in three words—early lumbar nephrectomy. The kidney should be removed with its capsule and any perinephric fat which is adherent to it. When dense adhesions render subcapsular enucleation necessary, the results are unsatisfactory, and the operation is apt to be followed by a persistent tuberculous sinus. If the disease is complicated by a perinephric abscess, nephrectomy must be deferred until the abscess has yielded to treatment. The kidney must never be incised to verify a diagnosis which should have been complete and certain before operation, otherwise the surrounding tissues will be infected and the wound may take months to heal. After operation a prolonged course of tuberculin should be given.

Treatment of the Ureter.—Most surgeons divide the ureter at a convenient distance from the kidney either with the cautery or between two ligatures after injecting iodine or carbolic acid. My own practice has been to remove the entire ureter whenever it was obviously infected, in the hopes of alleviating the bladder symptoms which persist in so many cases, but the results, though slightly better than those following nephrectomy alone, do not come up to expectations.

TECHNIQUE AND RESULTS.

In 52 cases operated on by myself and others, which I have been able to trace up to last July, nephrectomy was performed in 33, and in the remaining 19 the entire ureter was removed as well. The results are as given in Table I.

TABLE I.—Results of Nephrectomy and Nephro-Ureterectomy.

—	No. of cases.	Mortality.		Now quite well.	With bladder symptoms.
		Operative.	Late.		
Nephrectomy	33	4	3	15 (58 %)	11 (42 %)
Nephro-ureterectomy	19	0	3	10 (63 %)	6 (37 %)

Thus it will be seen that after the more extensive operation the number of apparent cures is slightly

higher, and the number of cases with bladder symptoms is slightly lower. An analysis of the cases with persistent bladder symptoms is of interest. (Table II.)

TABLE II.—Cases with Persistent Bladder Symptoms.

—	No. of cases.	Frequency only.	Frequency and pyuria.	Frequency and pyuria with tubercle bacilli.
Nephrectomy ..	11	3 (27 %)	7 (63 %)	1 (9 %)
Nephro-ureterectomy	6	3 (50 %)	1 (16 %)	2 (33 %)

If the small number of cases from which these figures are derived is of any value, they indicate

FIG. VII.

Lower end of ureter and base of bladder. (Drawn at an operation.)

greater benefit from the major operation. Judd states that the extensive operation necessary to remove the entire ureter greatly increases the operative risk, but this is not my experience, as in 19 cases there has not been any operative mortality. If performed by the technique I will now briefly describe the risks are slight, and the shock is no greater than after simple nephrectomy.

After freeing the kidney and ureter the pedicle is ligatured and divided and the kidney is brought out of the wound. The subperitoneal fat is then separated from the ureter as far as the finger can reach, generally to the brim of the pelvis. The wound is now sutured, leaving the kidney, still attached to the ureter, hanging from its anterior extremity. The patient is then placed supine and the pelvic ureter is exposed by Kidd's incision (Fig. VI.); it is found easily as it has already been freed as far as the brim of the pelvis, and is as easily followed to the base of the bladder (Fig. VII.), where it is ligatured in two places, injected with carbolic acid, and divided (Fig. VIII.). An assistant then gives the kidney a sharp pull, when it comes away with the entire ureter attached. The lower wound is closed without drainage and the loin wound is drained for 24 hours with a piece of corrugated rubber.

Operative Mortality.

The records of 65 operated cases were examined; four died shortly after nephrectomy, one from shock, and three from uræmia, making an operative mortality of 6 per cent. In 35 of these cases which were under my own care there were no deaths from operation. If the deaths from uræmia (a cause which is rare in these days) be excluded, the operative mortality works out at 2 per cent., a figure which corresponds with other published records.

Late Mortality and Results.

I will now give you a brief summary of 48 of the above cases which were traced and of which I have complete post-operative details. In every instance I have either seen the patient recently or received a letter from him or his doctor. The urine of all who were not perfectly well and free from bladder symptoms was examined by a pathologist. Forty-two were living and six had died within two and a half years of the operation, either from phthisis or tuberculosis of the remaining kidney. The present condition of the 42 survivors is as follows: 25, or 60 per cent., are in good health and may be regarded as cured, and 17, or 40 per cent., are still suffering from bladder

FIG. VIII.

Ureter ligatured at base of bladder and injected with pure carbolic acid before division.

symptoms, either frequency only, or frequency and pyuria, and in three of these tubercle bacilli are still present in the urine. (See Tables I. and II.)

TABLE III.

Out of 42 cases—	8 are alive	3 years after operation.
4 " "	4 " "	" "
3 " "	5 " "	" "
5 " "	6 " "	" "
2 " "	7 " "	" "
4 " "	8-10 " "	" "
11 " "	10-17 " "	" "

Broadly speaking, the results of nephrectomy for unilateral disease in the 48 cases which were traced are as follows:—

12 per cent. are dead two and a half years after operation.
52 " " are cured.
35 " " still have urinary trouble.

It is interesting to compare these figures with those of the Mayo Clinic published by Judd and Scholl last March. In 29 years there were 863 nephrectomies for renal tuberculosis. Complete post-operative data were obtained in 611, with the following results:—

31 per cent. are dead.
58 " " are cured.
10 " " still have urinary trouble.

The figures of other writers, though varying slightly, are essentially the same, therefore it is fair to conclude that at the present day the operative mortality should not exceed 2 per cent., and the permanent cures should not be below 60 per cent.

Owing to the delay which so commonly follows the onset of symptoms, and the recognition and surgical treatment of renal tuberculosis, many patients of both sexes suffer from persistent bladder trouble (35 per cent. in my series), and males are prone to secondary genital tuberculosis. Frequency alone is due to a bladder which is contracted by long-standing

inflammation, and which will gradually dilate with time, though it seldom attains the capacity of the normal bladder. Hydrostatic dilatation is sometimes beneficial, but, generally speaking, it has little effect. One of my patients, operated on ten years ago, after a prolonged course of tuberculin advised by a physician, had such a contracted bladder that only a 2½ oz. distension was possible under deep anæsthesia. She is now able to retain urine for four or five hours, but this is exceptional. Frequency combined with pyuria is often due to a granuloma or a tuberculous ulcer of the bladder. For several years I have treated these conditions by diathermy "frizzling." The electrode is placed near enough to the ulcer to allow a shower of sparks to play on it, but care must be taken not to produce a severe burn, or perforation will follow the separation of the slough. Three males developed a troublesome stricture following tuberculous posterior urethritis. They all yielded eventually to tuberculin and careful dilatation with sounds. Four developed epididymitis, which in three was accompanied by vesiculitis and pyuria. In one the vesicle was converted into a large tuberculous abscess, which was opened and curetted extraperitoneally after orchidectomy, and in the other two Loughnane's operation of orchido-vaso-vesiculectomy was performed, and followed by rapid disappearance of the pyuria.

In conclusion, while admitting that the results of the surgical treatment of renal tuberculosis are not as good as they ought to be, yet I have no doubt that before long, when the medical profession as a whole has learned to regard all cases of mild "cystitis" with suspicion, and when the ureters of a patient with a sterile purulent urine are regularly catheterised, and the two specimens of urine are examined for tubercle bacilli, there will be a negligible operative mortality, a great increase in the percentage of cures, and a corresponding diminution in the troublesome genito-urinary complications.

DEWSBURY MATERNITY HOME.—A maternity home of ten beds provided by the town council of Dewsbury has been opened at Moorlands Hall. The mayor, in opening the home, said that in certain parts of the town there were a great number of homes unfit for the birth of children.

ROYAL SALOP INFIRMARY.—At the annual meeting, held at Shrewsbury, it was stated that during the past year the number of in-patients was 1605 and out-patients 1216. Some 210 parishes in Shropshire and the border counties were giving generous help, the sum contributed last year being £3500—that is, £700 in advance of the previous year. During the year the subscriptions were £6650 and the donations £3270. The income balanced the ordinary expenditure. It is proposed to inaugurate a joint appeal for 1,000,000 shillings for extension and improvement of the Royal Salop Infirmary, the Eye, Ear, and Throat Hospital, the King Edward VII. Memorial Sanatorium, and the Shropshire Orthopaedic Hospital. Of the £50,000 required, £6908 have been received.

A STUDY OF THE EFFECT OF DEEP THERAPY ON THE BLOOD IN LEUKÆMIA.

By W. L. WATT, C.M.G., M.D. MANITOBA,
IN CHARGE OF DEEP THERAPY RESEARCH DEPARTMENT, GUY'S
HOSPITAL; FORMERLY IN CHARGE OF X RAY AND ELECTRO-
THERAPEUTIC DEPARTMENTS, WINNIPEG GENERAL
HOSPITAL.

Assisted by

J. CARTER BRAINE, F.R.C.S. ENG.,
GRIFFITHS DEMONSTRATOR OF PATHOLOGY, GUY'S HOSPITAL.

FROM the days of Pusey, who, in 1902, was the first to X ray an enlarged spleen, this method of treatment has gradually come into general use. The technique usually employed was one of repeated exposures at intervals of a few days, using rays which we now designate as soft. More recently medium hard rays have been employed, a series of three exposures being given, one to the front, one to the side, and one to the back of the splenic area, the series being repeated every three to four weeks. In the following cases extremely hard rays only were used, limited to one exposure of the whole splenic area wherever possible. In the grave cases a series of three or four exposures was given, covering various parts of the body.

All dosages mentioned are based on the time it would take the rays generated at a voltage of 210,000 and filtered through zinc 0.5 mm. and aluminium 3 mm., to cause a skin erythema at the area exposed in three days, the distance of the tube target from the skin being 23 cm. This time is given a nominal value of 100, so that if a 60 per cent. dose is mentioned, this means that it takes 120 minutes to give a skin erythema dose at a distance of 50 cm., the actual time of exposure was 60 per cent. of this, or 72 minutes.

It will be noticed that the list of cases is a fairly representative one; this has only been made possible by the great kindness of the visiting staff of the hospital, who, often at great inconvenience owing to the lack of beds, have readmitted these patients for further observation and treatment if necessary. The blood examinations have been carried out by Mr. Carter Braine, the actual number of counts taken being about 450. His findings were most kindly checked by Prof. Stokes and others on various occasions, and the variation has never been more than 10 per cent., so that the counts as given can be considered as at least approximately accurate.

TABLE I. (CASE 1).—Blood Counts.

Hb, hæmoglobin. R.B.C., red blood corpuscles. Leucos., leucocytes. Lymphos., lymphocytes. Polys., polynuclears. Eosins., eosinophils. Basos., basophils. Monos., mononuclears. Myelos., myelocytes. Trans., transitionals.

CASE 1.—*Lymphatic Leukæmia.*—E. P., male aged 48 years, under the care of Dr. J. Fawcett. Twelve years ago patient had an operation for perforated duodenal ulcer. One year ago he had an attack of pneumonia and has never felt well since. Three months ago he noticed that his abdomen was enlarging and since then he has been greatly troubled with indigestion. A hernial protrusion has appeared in his operation scar. Examination revealed an enlarged spleen which reached two and a half inches beyond and below the umbilicus; the notch could be felt above and slightly to left. Blood counts are given in Table I.

CASE 2.—*Lymphatic Leukæmia*.—W. M., male aged 60, under the care of Dr. Fawcett. About October, 1923, patient noticed swellings in the groins, then in the axillæ, and later in the neck. The latter was accompanied by tinnitus aurium. He complained also of increasing pain in left shoulder and the sacral region. Examination revealed an enlarged spleen which reached beyond the umbilicus and one inch below a line drawn from the umbilicus and the anterior superior iliac spine. Blood counts are given in Table II.

TABLE II. (CASE 2).—*Blood Counts*.

Date.	Hb.	R.B.C.	Leucos.	Lymphos.	Polys.	Eosins.	Monos.	Myelos.
23/11/23 ..	59	3,800,000	180,000	92	7	0	0	1
7/1/24 ..	76	4,100,000	15,200	74	22.5	0.5	3	0
12/2/24 ..	96	5,100,000	8,500	45	51	0	4	0

Oxidase reaction on 21/11/23, only 10 per cent. reduction. This patient was subsequently lost sight of. Only recently has it been possible to obtain further information through the kindness of the doctor who subsequently attended him. His letter reads as follows: "In answer to your letter re M. He died in the infirmary on 21st May. I sent him there at the end of March as he was confined to bed and his home was not suitable for nursing him. At that time he had moderate enlargement of the spleen, extreme wasting, an evening temperature, pain in back, and glands were enlarged, but not very." No further details could be obtained from the infirmary as a post-mortem was not held, and the cause of death was given simply as leukemia. In the light of experience with even apparently much graver cases, it is unfortunate that further radiation was not given, especially if death was due to a recrudescence of the disease.

CASE 3.—*Lymphatic Leukæmia*.—A. U., male aged 49, under the care of Dr. Fawcett. Three years ago patient noticed a few lumps in left side of the neck which have gradually increased in size. Two months ago he noticed his abdomen becoming larger. Three weeks ago swellings appeared in the axillæ and groins. Patient states he has felt ill for past six months. On admission he was slightly jaundiced and had oedema of the hands and feet. Abdominal examination revealed an enlarged liver which extended to five finger-breadths below the costal margin and an enlarged spleen which extended to two and a half inches to the right of umbilicus and the same distance below. The notch could be felt above and to the left of the umbilicus. There was considerable free fluid in the abdomen. Radiologist reported that the chest showed enlarged root-shadows and infiltration of both lungs. Glands: Neck, both sides, especially the left, numerous, largest size of hen's egg. Groins: Both sides, numerous, largest size of walnut. Axillæ: Both sides, numerous, largest size of hen's egg. 7/1/24: Oxidase count by Prof. Stokes—98.5 per cent. lymphatic type. 14/1/24: A large mass of glands have developed under the left ear, following attack of quinsy. The spleen has further enlarged. 20/1/24: Glands incised and pus freely evacuated. Bacteriological report: A pure growth of *Staphylococcus aureus*. 21/2/24: Temperature normal. Pulse 80-95. Blood counts are given in Table III.

TABLE III. (CASE 3).—*Blood Counts*.

Date.	R.B.C.	Hb.	Leucos.	Lymphos.	Polys.
5/1/24 ..	3,240,000	50	340,000	99.5	0.5
9/2/24 ..	3,000,000	40	400,000	98.5	1.5
6/3/24 ..	2,880,000	48	180,000	95	5
2/4/24 ..	3,000,000	48	16,000	86	14
1/5/24 ..	3,800,000	60	15,600	88	9
30/5/24 ..	3,800,000	64	21,600	84	14

General Notes.—1. The lymphocytes remain persistently above the polynuclear, so that there is no crossing-over. 2. The red blood corpuscles and hæmoglobin after ten weeks begin steadily to rise. 3. Patient has received no further treatment for 14 weeks. He has been at home convalescing. He reported for examination on June 1st. His spleen was 7 cm. to the left of the umbilicus. His liver was smaller, reaching to one inch below the umbilical line. All glands were smaller and softer. Since this date he has been seen as an out-patient fortnightly. There has been a noticeable improvement in his general health. His blood count of leucocytes has remained practically stationary in the neighbourhood of

20,000. The liver and spleen have slowly decreased. All glands have diminished except the submaxillary, which recently enlarged. He was therefore readmitted to hospital on July 1st. His spleen now reaches 10 cm. from the umbilicus and is only about 2 cm. below the umbilical line, while the liver is now about the same distance above this line. As his leucocyte count is still only in the neighbourhood of 20,000 it is thought that a 30 per cent. deep therapy radiation to the submaxillary regions on each side will be sufficient.

CASE 4.—*Myelogenous Leukæmia*.—R. G., male, aged 53, under the care of Dr. A. F. Hurst. In July, 1923, patient consulted his doctor for shortness of breath. Examination revealed the spleen to be much enlarged. It has steadily increased in size up to time of admission, 21/2/24. Examination revealed an enlarged spleen, which was 2 inches to the right and 4 inches below the umbilicus. The liver is also definitely enlarged. Blood counts are shown in Table IV.

TABLE IV. (CASE 4).—*Blood Counts*.

Date.	Hb.	R.B.C.	Leucos.	Myelos.	Polys.	Lymphos.	Eosins.	Basos.	Monos.

CASE 5.—*Myelogenous Leukæmia*.—K. S., female, aged 34, under the care of Dr. Fawcett. History of amenorrhœa from September, 1922, with steady increase in size of abdomen. On admission a large hard tumour could be felt extending from pubis to half-way between umbilicus and sternum. Pelvic examination revealed presence of tumour mass there also. Splenectomy, 12/3/23. Blood counts are given in Table V. and V.A.

TABLE V. (CASE 5).—*Blood Counts, 1923*.

Date.	R.B.C.	Leucos.	Melos.	Polys.	Lymphos.	Mast.

4/9/23	2,400,000	121,000	—	—	—	—

TABLE V.A.—*Blood Counts, 1924*.

Date.	Hb.	R.B.C.	Leucos.	Myelos.	Polys.	Lymphos.	Eosins.	Basos.
12/3/24 ..	75	3,900,000	220,000	50.5	30.5	5.5	4	7.5
8/4/24 ..	90	5,000,000	9,400	42	45	6	1.5	5.5
9/5/24 ..	100	4,800,000	10,600	3	77	12	2	6
28/5/24 ..	100	5,000,000	11,000	2	75	17	3	2

The effect of splenectomy was first a temporary rise of leucocytes followed by a decline, which apparently reached its maximum in about three months. From this time there was a gradual rise to more than double the original count. The effect on the red blood corpuscles was unfavourable, and even six months after the operation the count was only 2,400,000. Her symptoms on readmission were complaints of general weakness and of being easily irritated and excited.

CASE 6.—*Polynuclear Type Leukæmia*.—F. B., female aged 60, under the care of Dr. Hurst. 13/3/24. History of six months' illness, with breathlessness and palpitation. Later she noticed swellings in axillæ and neck. She has gradually become weaker, and seven days before admission was compelled to go to bed. Latterly she has had a very troublesome cough. X ray report: Irregular rounded shadow opposite root of right lung. The right diaphragm has limitation of movement. Respiratory system: Diffuse bronchitis. Abdomen: Spleen four finger-breadths below costal margin. Glands: A mass of glands along posterior border of sterno-mastoids, numerous glands in axillæ, some as large as walnuts and a few in the groins. Blood counts are given in Table VI.

TABLE VI. (CASE 6).—*Blood Counts.*

Date.	R.B.C.	Hb.	Leucos.	Polys.	Myelos.	Lymphos.	Monos.
		%					
12/3/24 ..	3,950,000	70	144,000	84	9	5	1
20/3/24 ..	3,580,000	—	130,000	73	18	8	0
2/4/24 ..	3,800,000	85	90,000	80	11	6	2
12/4/24 ..	4,200,000	—	40,000	78	11	10	1
20/4/24 ..	—	—	38,000	83	5.5	8	3.5

This case showed previous to deep therapy marked hourly variations between 80,000 and 144,000.

This patient subsequently had her teeth extracted for pyorrhœa, commencing April 24th. Gradual extraction was carried out at intervals of a few days. On May 24th she developed an acute inflammation of the skin in the right cervical region about level of larynx, which rapidly sloughed. She was readmitted to medical wards May 31st, transferred to surgical June 5th, and died June 17th. The infection was streptococcal, and the erysipeloid condition spread over the right chest and shoulder, with sloughing of the skin. The left arm became swollen and inflamed, and eventually several suppurating sinuses formed.

Post-Mortem Report.—Emaciation, extensive erosion of the skin over right shoulder and neck anteriorly, suppuration of left arm from several sinuses, great œdema of the arms. Mucopus in bronchi. Dense adhesions right lung. This lung full of semi-hard nodules. A dense mass around left root. Lung adherent to pericardium. Spleen enlarged, weight 350 g.

The question naturally arose as to whether the condition was of the nature of an X ray burn. As, however, she only received three exposures in all, a 50 per cent. skin erythema dose to the lower left chest from in front, and a 45 per cent. dose to the same chest from behind and a 35 per cent. dose to the lower abdomen, this could be absolutely ruled out. The cervical regions and the right chest received no rays whatever. An X ray burn is invariably limited to the area of exposure.

CASE 7.—Myelogenous Leukæmia.—C. J., male aged 39, under the care of Dr. H. French. Patient was well until 18 months ago, when he was treated for carbuncles and has never felt right since. Latterly his general weakness has become much more pronounced, and his abdomen has steadily increased in size. His condition on admission was serious. The abdomen was enormously swollen. The spleen reached to the left anterior superior iliac spine and practically filled the pelvic cavity. The liver also was greatly enlarged, being only separated from the upper border of the spleen by about one inch. He has had a severe incessant cough for past two months, and on examination œdema of the bases of both lungs was present. Œdema of feet and legs was present, and considerable free fluid in the abdomen. His former admission to hospital was July 4th, 1923, and after a short stay he was sent to the X ray department for treatment as an out-patient. He was given in all 54 exposures to the splenic area, between this date and March 14th, 1924. There was considerable benefit at first, but from the beginning of the year he became increasingly worse, until on readmission his condition was as above described. Blood counts are shown in Table VII.

TABLE VII. (CASE 7).—*Blood Counts.*

Date.	Hb.	R.B.C.	Leucos.	Myelos.	Polys.	Lymphos.	Eosins.	Basos.	Hyaline.
	%								
5/7/23	36	4,560,000	325,000	86	19	3	2	3	7
26/7/23	30	—	250,000	66	28	6	—	—	—
29/7/23	40	3,660,000	430,000	—	—	—	—	—	—
8/4/24	38	2,260,000	580,000	70	21	5	1	3	—
2/6/24	56	4,000,000	146,000	59	30	5	—	6	—

A blood count previous to deep therapy showed that in the same day there was a remarkable variation of between 440,000 and 600,000.

CASE 8.—Myelogenous Leukæmia.—W. W. M., male aged 43, under the care of Dr. Hurst. History of duodenal ulcer since 1919. First admitted to hospital 2/4/23, discharged 18/5/23. He was greatly improved for about nine months, then an acute attack of abdominal pain. Readmitted on surgical side, but as the spleen was found to be enlarged, he was treated medically. Present condition: Spleen somewhat

enlarged, about three inches below the costal margin. The liver greatly enlarged, reaches to umbilical line. Marked bronzing of the skin. Axillary glands enlarged. Extreme general weakness. Patient since admission has been failing rapidly, his red blood corpuscles have dropped from 6,000,000 to 2,000,000, his hæmoglobin from 40 per cent. to 28 per cent. His leucocyte count exhibits extreme variations between 400,000 and 240,000. He has no desire for food, and is extremely listless. The fæces contain altered blood. Table VIII. gives the blood counts.

TABLE VIII. (CASE 8).—*Blood Counts. Before and After.*

Date.	R.B.C.	Hb.	Leucos.	Polys.	Myelos.	Trans.
		%				
26/4/24 ..	6,000,000	40	—	40	—	—
20/5/24 ..	3,400,000	35	250,000	—	—	—
3/7/24 ..	2,050,000	28	346,000	40	49	4
10/7/24 ..	2,146,000	32	200,000	49	36	6
24/7/24 ..	3,500,000	44	120,000	57	27	4
12/8/24 ..	4,000,000	60	100,000	53	25	3

The serious condition of the patient was so obvious that it seemed best to give only small radiations repeated at intervals of one week or longer. By this means it was hoped to cause a rather slow destruction of the leucocytes, with at the same time a decidedly stimulating effect on the red blood corpuscles and the hæmoglobin.

Deductions from the Cases.

These cases would appear to justify the following deductions:—

1. From the commencement of the exposure to deep therapy radiations the leucocytes begin to fall, and the destruction is most marked during the last half of the radiation.

2. The subsequent fall may be interrupted by a fleeting primary reaction coming on two to five hours afterwards, and by a secondary reaction which comes on two to five days afterwards and usually lasts 24 hours.

3. The susceptibility of the individual leucocytes varies with the type of leukæmia. In the lymphatic the lymphocyte is the most susceptible, in the myelogenous the myelocyte, and in the polynuclear the polynuclear. However, no matter which type it is, the polynuclear, the lymphocyte, and the myelocyte, if present, all share in the fall, and also in the primary and secondary reactions.

4. With the fall of the leucocytes there is a rise of the red blood corpuscles and the hæmoglobin. Conversely, when the red blood corpuscles and hæmoglobin fall the leucocytes rise.

5. The spleen steadily diminishes in size without undue rapidity and without any apparent deleterious effect. Likewise the liver, when enlarged, and also the lymph glands, similarly diminish in size.

6. The health of the patient steadily improves and in uncomplicated cases, without any serious disturbance of compensation, they are soon back to full-time work.

7. Splenectomy is not a contra-indication, as the effect is almost as striking as if this organ were present.

8. Patients already subjected to a long course of ordinary X rays, with final failure to respond, are still susceptible to deep therapy with considerable hope of improvement.

With subsequent radiations, in the lymphatic type, if the lymphocytes still predominate, they are the most susceptible, whilst the polys are but slightly affected. However, if the crossing over has taken place and the polys are now in the ascendent, they become the more susceptible, whilst the lymphos remain more or less stationary. They may even rise as the result of the radiation. The same remarks apply to the other types of leukæmia. The secondary reaction is still present. The reduction in the size of the spleen is more marked than with the first radiation. The rise of the red blood corpuscles and hæmoglobin may be more marked. There is usually a more noticeable improvement in the patient's general condition.

To attempt an explanation of these various deductions brings one at once into the realms of controversy. Heinecke, in 1913, demonstrated the effect on the spleen itself. One hour after radiation the destroyed leucocyte nuclei were practically all massed in the centre of the follicles and only a few in the periphery of the follicles. The destruction was at its maximum four to six hours later. Phagocytes now appeared which engulfed the nuclei and they in turn disappeared in eight to ten hours. After 12 to 24 hours no nuclei or phagocytes were visible. The follicles became cell-poor and free of lymphocytes. With stronger doses the follicles themselves are destroyed, and only the fixed cells left. The diminished spleen becomes of a dark-brown colour. There is an extraordinary increase of pigment, which normally is scanty. The round cells are destroyed and replaced by vacuolated epithelioid cells.

Direct cell injury is the outstanding feature. The nucleus and the protoplasm are especially sensitive. Wassermann demonstrated that it is the reproductive element of the nucleus which is especially vulnerable, as opposed to the nutritive element. The former he designated as the geniceptor and the latter the nutriceptor. Nurnberger demonstrated in his researches on the uterus of white mice that the nucleus shows a change in staining, it loses its acid character and stains with basic dyes, that it loses its normal chromatin hue and breaks up into larger and smaller chromatin globules. Halberstadter, in experiments on apes with trypanosomes, found that if sufficient dose was given to injure but not to destroy the trypanosomes, they no longer had the power of reproduction, and so gradually died off without doing any injury. By giving larger doses Wassermann proved that not only the geniceptors, but also the nutriceptors, were destroyed, and the whole organism died.

The sensibility of a cell depends upon the rapidity of its reproduction; the quicker this takes place the more vulnerable it is. The younger the cell the more vulnerable it is. The less specialised its function the more susceptible it is. The leucocyte is extremely susceptible, a 20 per cent. unit skin dose being quite sufficient to destroy its nucleus and the whole cell.

The primary reaction is possibly due to the irritative effects of the destroyed leucocytes causing the various storehouses throughout the body to throw their reserves of leucocytes into the blood-stream. The secondary reaction, however, may be due to the same irritative effects of the destroyed leucocytes on the cell-producing centres themselves, causing increased and rapid proliferation of more or less immature leucocytes, which, in turn, are especially vulnerable to the toxic agents circulating in the blood. The subsequent decline is probably an inhibitory action on the cell-producing centres by the toxins limiting their activity. The chief effect would be on the geniceptor element of the nuclei of the reproducing cells.

The leucocytes that survive the bombardment of the rays are the fittest and the strongest, as the weaker, the younger, and the more immature, are the first to be destroyed, and one feels inclined to believe that after the secondary reaction and subsequent decline, and the tissues have returned to a more or less normal condition, the leucocytes now formed have acquired a definite new characteristic; they are more resistant to the rays and might be designated as gamma leucocytes. It is probable that the extraordinary feeling of well-being that so frequently follows deep therapy radiations is due to the presence of these gamma leucocytes in the blood as well as the accompanying rise of the hæmoglobin and the red blood corpuscles which may likewise have acquired the gamma quality. Many remarkable results of the rays could be explained on some such supposition, and it is possible that one of the widest fields of usefulness of these rays will be in the application of stimulating doses to the red blood corpuscles, with slightly destructive doses to the leucocytes, repeated

at intervals of four to six weeks, and so to keep up what one might call a positive gamma stage over long periods. At the present time this is being more or less empirically done by many workers on the Continent in tuberculous and other chronic lesions.

For accurate results all blood counts must be most carefully carried out. As far as possible the same observer, using the same pipettes, the same counting-chamber, the same technique, the same conditions of time of day and relationship to food. In active cases this is absolutely necessary, as the hourly variations of the leucocyte count may be in the hundreds of thousands.

The results obtained would indicate that the success of the earlier methods was due to the cumulative effects of the few hard rays which were emitted during each application. The danger of repeated applications of soft rays has been irritation, both to the skin and the deeper structures with inflammatory changes and adhesions. In addition a great drawback has been that it made the patient a semi-invalid. He became an out-patient attending two or three times a week for treatment over prolonged periods of many months or years. By the use of deep therapy the danger of dermatitis is reduced to practically nil, as one never gives more than a 60 per cent. radiation. The rays are so penetrating that one can use any part of the body to obtain the effect desired. After the patient's primary stay in hospital he can usually return to his work, and he need not again leave it for weeks or months, and even when it is necessary for his readmittance, his stay need not be more than five to seven days.

Indications for Further Treatment.

These are: (1) Any marked increase in the pathological leucocytes, especially when accompanied by a drop in the hæmoglobin and the red blood corpuscles. (2) The presence of enlarged glands in other parts of the body which show no signs of diminishing. These should be radiated separately. (3) Failure of the spleen to diminish considerably in size, or its subsequent enlargement after having diminished. (4) The general health of the patient deteriorating.

It is to be noted that the actual number of leucocytes present in the blood is not given as one of the indications. It would be quite easy to set an arbitrary figure of, say, 20,000, above which would be an indication for further radiation. If accompanied by any of the indications as given above, it would be quite correct to subject the patient to further radiation, but otherwise one feels it would only be doing harm.

The contra-indications for further therapy are: (1) Leucopenia. This would indicate that an excessive dose had been given. (2) Persistent diarrhoea, due also to an excessive dose. (3) An actual increase of the pathological types of leucocytes after the radiation, unless only a small trial exposure had been given, in which case it would still be safe to give a full 60 per cent. skin dose. (4) Deterioration in the patient's general health with failure of the hæmoglobin and red blood corpuscles to rise.

Dangerous Fields of Exposure.

The liver should, generally speaking, not be exposed to the rays as there is much more liability to Röntgen toxæmia, a systemic condition with headache, fever, nausea, vomiting, diarrhoea, &c. If, however, it is excessive in size and does not reduce with the spleen, small doses (30 per cent.) to limited areas may be tried. The rays, especially the central rays, should not be directed towards the suprarenals, as they, like the testes and ovaries, are extremely susceptible to the rays.

Prognosis.

With the return to a practically normal condition the stage of compensation may be said to be reached. This stage may last for months, but the patient should be instructed to report once a month to his doctor or to the hospital, as far as possible at the

same hour of the day. A blood count should be taken and his general condition thoroughly gone into. If the indications point to a recrudescence of the disease, then arrangements should be made for an immediate radiation. The opportunity could be taken of radiating enlarged glands if present, or the long bones, so as to save the splenic area for any serious relapse where an immediate and marked effect is desired.

The duration of the stage of compensation is of necessity impossible to state. We know that it can last for three months or longer. This will mean that in the ordinary type of cases without a severe grade of failure, with marked enlargement of the liver, jaundice, oedema of the lungs, ascites, &c., it can reasonably be hoped that the maximum hospital treatment will not be more than one month in a year. The remaining 11 months the patient should be able to follow his usual occupation. The long interval between the radiations should help to lessen the risk of a marked diminution in effect of the subsequent radiations and so permit a greater expectancy of life with fairly good health.

In any particular case there are two indications of great importance in the prognosis. One is the rapid return to the normal relation and percentages of the various types of leucocytes, with a concurrent disappearance of the pathological types from the blood. The other is when, after subsequent radiations, we no longer get any disproportionate fall of the leucocytes, but all are equally affected. This, of course, means that there is no longer an over-production of any one type, and with the over-production the presence of many weak and immature and defective cells in the blood. The failure to obtain these two conditions with one or more radiations is indicative that the prognosis is bad.

The question as to whether a combination of splenectomy and deep therapy would be the best method of procedure is difficult to answer. In the one case of splenectomy under observation the effect was only a temporary one. The unfavourable sign was the marked and persistent diminution of the hæmoglobin and the red blood corpuscles. Notwithstanding the absence of the spleen this case responded to deep therapy extremely well, and the disappearance of the myelocytes from the blood with the return to a practically normal blood count was accompanied by a marked rise of the hæmoglobin and the red blood corpuscles, so that the patient is now at her work apparently in the best of health.

A series of observations were made as to the effect of the radiation on the blood pressure, pulse, and respiratory-rate. In four of the cases there was no appreciable change, either at half-way through or the end of one hour after the radiation. In two of the cases the blood pressure fell about 10 per cent. by the end of the radiation; this was accompanied by a slight slowing of the pulse-rate, but no change in the respiratory. In Case 6, which was of a very irregular type in every way, the readings were as shown in Table IX.

TABLE IX.—Blood Pressure Readings.

	Pulse.	Resp.	Systolic B.P.	Diastolic B.P.
First radiation—				
Before	78	22	110	74
After	76	22	108	72
Second radiation (interval 4 days) —				
Before	78	22	98	62
Half-way	84	23	93	62
End	84	22	105	72
1 hour later ..	84	22	103	70
2 hours later ..	82	20	95	64

The average age was 51 years. The average blood pressure was systolic 106, diastolic 76. The youngest patient of the series, aged 34, upon whom splenectomy had been performed, had the highest blood pressure—113–82 mm. Hg.

MELIOIDOSIS,

A DISEASE OF RODENTS COMMUNICABLE TO MAN.

BY A. T. STANTON, M.D. TORONTO,
M.R.C.P. LOND.,

AND

WILLIAM FLETCHER, M.D. CAMB.

(From the Institute for Medical Research, Kuala Lumpur, Federated Malay States.)

Two new items, tularæmia and melioidosis, have recently been added to our long account against the rodents. The damage done by these two diseases is infinitesimal when compared with the ravages of plague and, so far as our present knowledge takes us, they are of very limited distribution. This is particularly true of melioidosis which, apart from one case in Singapore, has been recognised nowhere except in the towns of Rangoon and Kuala Lumpur. It is difficult to believe that it is confined within such narrow bounds, and we are writing this short account in the hope that it will enable workers in other fields to recognise the disease when they meet it.

Melioidosis is very like glanders and, as in glanders, its symptoms vary according to the part or the organ of the body which is attacked; there are, indeed, absolutely no symptoms on which a trustworthy diagnosis can be based, and the true nature of the disease can be determined only by the cultivation of the causative organism from the lesions, or from the blood, sputum, or urine.

It was first recognised as a new disease by Whitmore and Krishnaswamy (1912). A year later, Whitmore (1913) published an excellent account of the malady under the title of "A Glanders-like Disease Occurring in Rangoon." Knapp (1915) and Krishnaswamy (1917) have made further contributions to our knowledge of this subject. We described new forms of the disease, and proposed for it the name "Melioidosis," as the physicians of ancient Greece had described by the name "Melis" a variety of conditions resembling glanders. We called the causative organism *Bacterium whitmori*, in order that Colonel Whitmore's name might continue to be associated with the bacillus which he was the first to isolate and describe; the name *pseudomallei*, which was the one he himself gave to the organism, being invalid (Stanton and Fletcher, 1921).

Our first encounter with the disease was in the form of a severe distemper among laboratory animals at Kuala Lumpur which broke out towards the end of 1913. The initial symptom was a milky discharge from the eyes and nose which was speedily followed by pulmonary involvement and death. Every case ended fatally. We isolated the causative organism but, though we noticed some points of resemblance to glanders, we did not suspect its connexion with Whitmore's bacillus or with a disease of man. In the year 1917, one of us (A. T. S.) saw several cases of the infection both in man and in animals, and found that they were due to one and the same bacillus. It is an organism with very marked specific characters, and was identified not only with the bacillus which had been the cause of the epizootic three years before, but also with that isolated by Whitmore from the human cases in Rangoon.

Epidemiology and Epizootology.

The causative organism has been found in the blood, the urine, the sputum, and, in one case, in the intestinal contents of man and animals. The outbreak among our laboratory rodents was due to the consumption of infected foodstuffs, which had probably been contaminated by the excreta of wild rats suffering from melioidosis. We have examined several wild rats (*Mus griseiventer* Bonhote) which had died from the disease contracted under natural conditions; and a domestic cat, which was supposed to have died from distemper, was found to have

succumbed to melioidosis. The disease may be conveyed to a rabbit or guinea-pig by pricking it with a needle dipped in a virulent culture, and it is possible that, occasionally, parasites may act as vectors of the infection; but we have not been able to prove that this is so. The disease which follows subcutaneous inoculation of the virus runs a course quite different from that which we saw in the laboratory outbreak, all the characteristic symptoms of which we readily reproduced experimentally by mixing cultures of *B. whitmori* with the animals' food, or by introducing the micro-organism into their noses with a platinum loop.

The problem of the way in which man contracts melioidosis remains unsolved. A large proportion of the cases observed by Whitmore, Knapp, and Krishnaswamy were morphine-injectors; at one time they considered that infection was carried by the syringe and they called the disease "morphine-injectors' septicaemia"; but none of the cases which have occurred in Kuala Lumpur have been injectors of drugs. We have not met with a case in which there was any history or evidence of a primary local lesion, such as occurs in animals inoculated with the virus. As it has been proved experimentally that animals can be infected by feeding, and as the onset of the disease in several human cases has been marked by very severe gastro-intestinal symptoms, we consider it in the highest degree probable that in man infection takes place through the medium of food which has been contaminated by rats.

The bacillus has been found in the blood, the sputum, the urine, and the discharge from the superficial lesions of human cases, and the lungs are almost invariably affected; one would therefore expect the virus to pass readily from the sick to the healthy, but this has not happened. We have not met with a single example in man where it has been possible to trace the infection to a previous case of the disease. Patients suffering from melioidosis have not been segregated; they have been treated in the general wards of hospitals, yet they have not communicated the disease to others. Only a small number of cases has been recognised up to the present time; 38 by Whitmore in Rangoon during 1911-12, 1 in Singapore in 1922, and 11 in Kuala Lumpur between 1917 and 1924 (4 in 1917, 1 in 1920, 3 in 1921, 2 in 1923, 1 in 1924). Of these 50 patients, 25 were Indians, 23 were Burmans, 1 was a Chinese, and 1 a European; with one exception all were males. Some additional cases have been seen by Knapp (1915) and by Krishnaswamy (1917) in Rangoon, since the publication of Whitmore's account of the disease in 1913. It is highly improbable that melioidosis is limited to the three towns where its presence has been detected; but its diagnosis is almost impossible in places where there is no laboratory, and even where laboratory facilities are available the disease may escape recognition by those who are unfamiliar with it.

Though the recognised morbidity-rate from melioidosis is very low, the case-mortality is very high. So far, only two men are known to have recovered from the disease. In one of these the recovery was only partial, for there remained suppurating sinuses leading to necrotic foci in the tibiae and tarsal bones when the patient was last heard of, two years after the commencement of his illness.

Ætiology.

Bacterium whitmori, the causative organism of melioidosis, possesses marked characteristics which distinguish it clearly from other pathogenic bacteria. Whitmore has described it in detail and in this short account we shall follow him closely. The bacilli, as seen in films made from the lesions of an infected organ, are about the size and shape of *B. mallei*. They stain readily with all the usual stains, but they are neither acid-fast nor Gram-positive. With Leishman's stain they show a well-marked bipolar staining, a character which is exceedingly useful in arousing early suspicion of the nature of the infection,

when a preliminary examination of films from diseased organs is being made. Growth upon all the usual culture media is rapid and luxuriant; it occurs under both aerobic and anaerobic conditions, though much more luxuriantly under the former. On the surface of liquid media a pellicle is formed which becomes a tough wrinkled skin in the course of four or five days. The two outstanding features of *B. whitmori* are, first, its motility in young cultures and, second, its curious growth on glycerine agar. Cultures on agar containing 5 per cent. of glycerine begin to acquire a wrinkled appearance in a couple of days; the growth rapidly extends until after a week's incubation it has become heaped up and rugose like a thick growth of tubercle bacilli (see figure). The organism liquefies gelatin and

Corrugated and mucoid cultures of *B. whitmori* on glycerine-agar with *B. mallei* for comparison. Seventy-two hours growth at 37° C. From left to right: *B. mallei*, strain A; *B. whitmori*, corrugated; *B. whitmori*, corrugated; *B. whitmori*, mucoid; *B. mallei*, strain, Muktesar; *B. mallei*, strain, Java.

curdles milk. It grows readily on potato, but without displaying any phenomena of diagnostic importance. *B. whitmori* produces no gas in carbohydrate media. Glucose broth, inoculated with the bacillus, becomes pink in a couple of days, if Andrade's indicator is used. The colour begins to fade at the surface of the medium almost before the deeper parts have begun to redden, and by the end of ten days it has gone. Some strains in addition to fermenting glucose form acid in saccharose, dulcitol, and mannitol, when they are first isolated, but they soon lose this property.

In addition to the usual form of the bacillus, which produces a corrugated growth on glycerine agar, we have isolated on several occasions a slimy mucoid variety, like the mucoid variety of *B. paratyphosus* (Fletcher, 1921). The mucoid has never been found except in association with the ordinary corrugated form; in one human case colonies of both types were isolated from an abscess in the patient's leg. On another occasion corrugated colonies were cultivated from the spleen of a rabbit, but mucoids were grown from its testes. We have shown, by agglutination and absorption tests, that the corrugated and the mucoid *B. whitmori* are serologically identical with one another. Moreover, if a mucoid colony be inoculated into broth, incubated for a few days, and then plated out, a number of corrugated colonies will be found mixed with the mucoids from which they have taken origin. We have not seen the reverse process occur in vitro—i.e., mucoids originating from corrugated colonies—although we have

adopted the method employed with success by Ainley Walker (1923) in the case of *B. paratyphosus*.

An investigation of 14 strains of *B. whitmori*, from human and from animal sources, by means of agglutination, absorption, and fixation tests, showed not only that we were dealing with a homogeneous group, but also that this group was closely related to some strains of *B. mallei* which we had obtained from India and Java. Its kinship with three strains of *B. mallei* from the national collection of type cultures proved to be very distant. These latter cultures were isolated probably from horses of the Arab strain, and we venture the hypothesis that the glanders bacillus which infects Arab horses differs serologically from that which attacks the country-bred ponies of the Far East. Horses are apparently immune to infection with melioidosis; we have attempted to infect both Arabs and country-breds by subcutaneous, intravenous, and intranasal inoculation, but without success.

Inoculated into the peritoneal cavity of a male guinea-pig *B. whitmori* gives Strauss's reaction, the classical test for *B. mallei*, provided that the culture is not so virulent, nor the dose so large, as to cause the death of the animal before the characteristic inflammatory enlargement of the testes occurs.

Animal Inoculations.

Rodents are readily infected by feeding, by inhalation, by subcutaneous inoculation, and by scarification of the skin. The subcutaneous inoculation of a freshly isolated and virulent culture of *B. whitmori* will cause the death of a guinea-pig, rabbit, or rat from septicaemia in less than 24 hours. If the quantity of the virus is smaller, or its virulence is less, or if it be inoculated by scarification, the result is a localised caseating induration which breaks down to form a sloughing ulcer. The lymphatic glands in the groins and scapular regions become enlarged and suppurate, and the animal dies, usually within about three weeks. If a guinea-pig be infected by feeding it on a culture or by painting *B. whitmori* on the nasal mucosa, it dies within two weeks or less with caseous ulcerating lesions of the mucous lining of the nose, enlarged tracheal glands, caseous deposits in the lungs, and sometimes in the spleen and other organs. We have fed three monkeys (*Macacus cynomolgus*) on culture of *B. whitmori*, with the result that one died with caseous patches in the lungs, but the other two escaped infection. Goats are susceptible; domestic fowls are not.

Morbid Anatomy.

The characteristic lesion of melioidosis is a small, yellow, caseous nodule which commences as a collection of polynuclear cells surrounded by a zone of congestion. By the time these nodules have become large enough to be visible to the naked eye, they consist of a mass of necrotic, caseous material containing a great number of chromatin fragments which are the remains of dead nuclei. The nodules have been found in almost every part of the body except the brain, and they coalesce to form large areas of caseation, particularly in the lungs. They sometimes break down to form abscesses in the viscera of man, but not in animals. Small abscesses are the commonest lesion in the spleen; in the liver larger abscesses are more frequent. The gall-bladder is sometimes thickened, and *B. whitmori* can be cultivated from the bile. On several occasions small superficial ulcers have been found in the caecum, but *B. whitmori* has not been grown from them.

The lungs are nearly always affected. When the disease is not far advanced, the nodules can be felt, like shot, within the substance of the lungs; they resemble miliary tubercles, except that they are less numerous and more scattered. When the process has gone further the lungs may be filled with large caseous masses; nodules in the lungs very rarely break down to form abscesses. The spleen is enlarged and frequently contains nodules and small abscesses filled with creamy pus. Nodules in the liver are

particularly prone to suppurate, producing multiple small, round, sharply demarcated abscesses filled with thick greenish-white pus. Abscesses may also be found in the subcutaneous tissue, in the muscles, and in connexion with the bones. It is not uncommon to find nodules on the peritoneum of animals, especially on the under-surface of the diaphragm and in the great omentum, but we have not seen these lesions in human cases.

Melioidosis in rats is characterised by massive caseation of the lungs; the contents of the thorax are converted into a caseous mass with the heart embedded in the middle of it. Smaller lesions may be found in the liver, kidneys, and testes. Sometimes there are large nodules in the substance of the spleen and on its surface; it then bears a striking resemblance to the spleen of a rat with resolving plague. A condition exactly similar to that seen in naturally infected rats may be produced by feeding them on cultures of *B. whitmori*, or by inoculating a small quantity of a laboratory culture at the root of the tail. If a very virulent culture is used, the animal may die from septicaemia in about 24 hours. Sometimes the resemblance to plague is very striking; a rat which had been fed on a culture, recently isolated from a human case of melioidosis, died five days later, and, post mortem, there was the intense subcutaneous injection and redness, associated with haemorrhagic enlargement of the cervical and axillary glands, which is seen in rats dead from plague. The condition of the lungs, however, was characteristic of melioidosis; they were largely converted into yellow caseous material which was so friable that they crumbled like a milk cheese when one attempted to grasp them with a pair of forceps. Great numbers of *B. whitmori* were found in films prepared from the lungs. The bacilli were almost entirely within large cells. No organisms were found in films made from the blood or the spleen, although *B. whitmori* was cultivated from them.

Symptomatology.

Melioidosis presents no cardinal symptoms upon which to base a diagnosis, consequently it is difficult to give a succinct account by which it may be recognised. The symptoms depend partly upon the virulence of the infecting strain and its initial dose, and partly upon the resistance of the patient and upon the region of his body in which the lesions are situated. There is no clinical resemblance between tuberculous meningitis and tuberculous disease of the hip-joint, yet both are due to infection with the same organism. Similarly, there are wide differences between one case of melioidosis and another; we have seen, on the one hand, acute septicaemic cases which resembled cholera, plague, or typhoid fever, and, on the other, localised infections with *B. whitmori* which were diagnosed as amoebic abscess of the liver, lobar pneumonia, or mastoiditis, according to the organ or part of the body in which the main lesions were situated and which bore the brunt of the disease.

When the infection is very virulent, the illness begins suddenly with vomiting, collapse, and diarrhoea so severe that a tentative diagnosis of cholera has been made on more than one occasion. The four cases which occurred in Kuala Lumpur during 1917 all began in this way and all were fatal. In these very acute cases a reaction usually occurs, on the third day the temperature rises and assumes a swinging septic character; in one instance a patient actually died during the stage of collapse, 72 hours after the beginning of his illness. When the initial infection is less virulent, there is no preliminary collapse but fever is high from the commencement, and the patient passes quickly into a typhoid condition. If he survive the initial septicaemia, the organisms establish themselves in various parts of the body, where they multiply and form caseous or pyaemic foci. There are nearly always some signs of pulmonary involvement, and the lungs are found to be diseased in 90 per cent. of the cases examined after death. In one patient there were nodules in the substance of the

kidneys and ulceration of the mucous membrane of the bladder. In this case the outstanding symptoms were those of severe acute cystitis. Three of the patients seen in Kuala Lumpur suffered from skin lesions; in one a generalised pustular rash broke out the ninth day; in another, a pustule, from which *B. whitmori* was cultivated, appeared on the chest a week after the beginning of illness; in the third case there were numerous purulent subcutaneous abscesses and hæmorrhagic bullæ. Late in the course of the disease, should the patient reach this stage, abscesses may develop in connexion with the bones. These abscesses show little tendency to heal when opened and they form sinuses leading down to soft necrosed bone.

To sum up, some of the most acute cases resemble cholera or plague; others, which have a high temperature from the beginning, resemble malaria, enteric fever, or general tuberculosis; yet others find their way to the dysentery wards. If pustules and abscesses appear, a diagnosis of acute glanders may be made; while the bone lesions which appear later on resemble tertiary syphilis or chronic tuberculosis. Delirium is a common symptom, and we have seen one unfortunate patient who was confined in a cell because he was supposed to be afflicted with acute mania.

Prognosis.

With two exceptions, every person known to be infected with melioidosis has died; of these two exceptions, one recovered after a long illness, the other was still an invalid with abscesses, sinuses, and chronic suppuration in the bones of his feet and legs more than two years after the commencement of the malady.

Diagnosis.

As we have stated already there are no definite clinical signs by which the disease can be recognised; a certain diagnosis can be made only by cultivation of the causative organism. A "positive" agglutination reaction is of value as presumptive evidence, particularly if the titre of the serum increases after an interval, but this reaction is obviously of little value in the diagnosis of the disease in its more common acute form.

The nature of the disease has been recognised during the life of the patient in only five of the 50 cases of which we have the details. In one of these five cases *B. whitmori* was cultivated from the blood, in another from the urine, in another from a pustular eruption, in another from an abscess in the parotid, and in the fifth the suspicions aroused by a "positive" agglutination test were confirmed by the cultivation of the bacillus from an abscess which appeared later.

B. whitmori has been cultivated from the blood and urine of human cases and also from pustules and abscesses when these have been present. In one case of infection in a rabbit it was cultivated from the intestinal contents. The inoculation of media with blood obtained by splenic puncture is useful in clearing up a doubtful diagnosis. When the lungs are involved, as they usually are, the examination of the sputum or of material obtained by puncture of the lung may make the diagnosis clear. In cases of obscure fever, associated with enlargement of the liver, this organ should be explored with a needle and glycerine-agar slopes and animals should be inoculated with material thus obtained. Whenever an abscess of the liver is aspirated or drained, glycerine-agar and guinea-pigs should be inoculated with the pus. Some cases of abscess of the liver due to *B. whitmori* have been mistaken for amœbic lesions.

Melioidosis is a rare disease in Kuala Lumpur; we have been keenly on the watch for it, not only in the post-mortem room but also among the rats examined in connexion with routine plague work. In Rangoon, where it has been known to exist for 14 years, it has not become common. But all the great epidemic diseases must have had small beginnings, and it is well that we should be on our guard against such a painful and fatal malady as melioidosis.

TUBERCULIN TREATMENT IN EXPERIMENTAL TUBERCULOSIS.

By L. S. P. DAVIDSON, M.B., Ch.B.,
M.R.C.P. EDIN.

(From the Department of Bacteriology, University of Edinburgh.)

IN view of the claims made by certain clinicians in favour of tuberculin therapy, the absence of experimental proof in support of this form of treatment is specially significant. The apparent discrepancy between the clinical and laboratory findings may be explained by a study of experimental tuberculosis in laboratory animals.

The failure of tuberculin as a specific and certain cure is now universally admitted. In fact, it is open to question whether tuberculin therapy possesses any real value, and whether the favourable results claimed from its use are not derived from general sanatorium régime. The majority of tuberculosis specialists, however, state that tuberculin treatment is of undoubted value, but even its most ardent supporters advance its claims with certain important reservations. Clinical experience is essential if satisfactory results are to be obtained. The physician must take into consideration (1) the site and extent of the lesion; (2) the type of the disease, whether acute or chronic, stationary or spreading, febrile or afebrile; (3) the general health of the patient. Having assessed all the available evidence, he may then be able to judge the correct dosage. After each dose the local, focal, and general reactions must be considered before estimating the next. No two cases can be treated alike, and success is essentially a function of experience; for no benefit will accrue if the case is unscientifically handled, but actual harm, or even death, may result from an excessive focal reaction with aggravation of the lesion and consequent serious systemic effects.

Difficulties Attending Experimental Investigations of Tuberculin Therapy.

The difficulties of the laboratory worker who attempts the tuberculin treatment of experimentally infected animals (e.g., guinea-pigs) can thus be understood. The appropriate initial dose, the subsequent ones, and the intervals between them can only be estimated empirically. Little or no information is known regarding the reactions of the animals to the antigen. Moreover, for any immediate conclusions to be drawn from the experimental results, a considerable number of animals must be used in order to eliminate the fallacies due to wide individual variations. Thus, in any scheme of experiments in which batches of animals are treated with the same doses at fixed intervals, the consideration of each individual case on its own merits is lacking.

In addition there are further difficulties. While it is well recognised that the guinea-pig is extremely susceptible to tuberculosis, only those who have actually carried out experimental work on the subject can realise to what extent individual guinea-pigs may vary. Thus in the publication of the Royal Commission on Tuberculosis it is stated that in one batch of animals injected with the same dose at the same time, the survival periods varied from 39-244 days. In the experiments about to be described it varied from 21-180 days. In other words, a definite minimum

(Continued from previous column.)

lethal dose acting within a reasonable time cannot be established. Another fallacious statement which is constantly being made is that if a guinea-pig has tuberculosis it progressively loses weight. This only occurs either when the animal is extremely susceptible or when the dose is excessive. In the event of the animal having a moderate resistance, or when the dose of tubercle bacilli is small, it may steadily gain in weight. Eventually, however, when the tubercle bacilli have overcome the resistance of the animal and the infection has become widespread, there is progressive loss in weight, followed by death. Erroneous conclusions, therefore, may be drawn if these facts are not realised.

A further important consideration in evaluating experimental results is the following. It must not be taken for granted that, because a discharging ulcer dries up, or a lymphatic gland, previously soft, becomes hard and shotty to the touch, or fibrosis is seen on microscopic examination in an organ removed at a post-mortem, that these observations indicate general healing, much less cure. Prof. E. H. Kettle¹ clearly showed in his paper on the criteria of cure in experimentally infected animals that in untreated guinea-pigs one gland might be fibrosed while the next was caseous; that even in one organ, such as the spleen, one part might exhibit signs of healing, while in another area there was active spread; that on careful microscopic examination patches of active disease might be found in areas of fibrosis. In short, it is typical of tuberculosis that the disease heals in one area while it spreads in another.

In consequence of these pathological findings in untreated guinea-pigs, fibrosis indicates only that a certain amount of cure has taken place in the area examined. It does not contra-indicate the evidence of active tuberculosis elsewhere. In my experience of the disease in guinea-pigs such active lesions will invariably be found. The only proof of cure is the survival of treated animals with death of the controls. These considerations indicate the difficulties and fallacies in any attempt to estimate the value of tuberculin treatment in experimentally infected animals.

The observations to be described form part of a more extensive investigation into the effect of physical and chemical processes on the antigenic values of bacterial vaccines.

Objects of the Investigation.

Guinea-pigs were injected with living tubercle bacilli, and then treated by various vaccines of the tubercle bacillus in order to ascertain (1) whether benefit or cure resulted, and, if so, which type of vaccine was the most efficient; or (2) if actual harm resulted.

Vaccine Used.

It was originally intended that three types of vaccine should be tested: (1) the ordinary heat-killed saline bacillary emulsion; (2) a detoxicated vaccine; (3) a defatted or diaplyte vaccine (Dreyer). As no undiluted diaplyte antigen could be obtained from the Oxford laboratory, the work on this vaccine was held over. Since then, however, Kettle has investigated this question, using undiluted diaplyte antigen, and has kindly allowed me to quote his results.

Ordinary Vaccine (Bacillary Emulsion).—This was prepared by growing a recently isolated strain of the human type on Dorset's egg medium. The surface growth was removed, weighed, and evenly emulsified in saline so that each cubic centimetre contained 1 mg. of heat-killed tubercle bacilli. By means of dilutions the requisite doses were made. This vaccine will be referred to as the "bacillary emulsion."

Detoxicated Vaccine.—A subculture of the same strain used for the "bacillary emulsion" was detoxicated by Dr. David Thomson, the originator of the detoxicating process. He prepared a vaccine containing the alkali soluble products

of the organism, each cubic centimetre representing 100,000 million bacilli. I am indebted to Dr. Thomson for making this and other detoxicated vaccines, and for his continued interest in these investigations.

Experimental Animals.—Forty-five guinea-pigs obtained from the same source were weighed and divided into three groups (A, B, and C) of 15 in each. On Dec. 15th the animals in group A received 1/100 mg. of living tubercle bacilli subcutaneously in the groin. Likewise group B received 1/500 mg., and group C 1/1000 mg. Owing to the severe cold about Christmas time, several animals in each group died. This was in no way connected with the injections, as numerous stock animals also died at the same time. Only those animals surviving for a minimum of three weeks are included in these results. On Jan. 18th two guinea-pigs died, showing definite evidence of tuberculosis. Treatment was then started—i.e., one month after the injection of living bacilli. Eight guinea-pigs were left untreated as controls. Nine were treated with detoxicated vaccine, and eight with the bacillary emulsion. The animals were weighed and injected with progressively increasing doses at weekly intervals.

Results.

In every case tuberculous disease was present either when an animal died after progressively losing weight or was killed after continually gaining weight. The guinea-pigs which died in a comparatively short time showed very advanced disease in every organ, while the animals killed at the end of the investigation only showed early lesions. The investigation was concluded on March 25th—i.e., about 100 days after the injection of living tubercle bacilli. With the exception of three animals which were kept to ascertain the length of their survival, all remaining guinea-pigs were killed and their organs subjected to microscopic examination. These animals, despite the fact that palpable inguinal glands were present, appeared to be in good health and had increased in weight.

Examination of the Weight Charts.—Examination of the weight curves of the 17 treated guinea-pigs shows that no benefits have accrued and no immunity has been produced. In fact, the reverse is the case, as the eight control animals show the largest proportional gain in weight. Table I. clearly indicates the results.

TABLE I.

	Average weight in grammes.		Average gain or loss.	Percentage gain or loss.
	Before treatment.	After treatment.		
Controls—				
8 guinea-pigs ..	357	487	+130	+36
Detox. vaccine—				
9 guinea-pigs ..	438	461	+ 23	+ 5
Bacillary emulsion				
8 guinea-pigs ..	423	465	+ 42	+10

On examination of the table of weights of control animals compared to animals treated with diaplyte antigen, published by Kettle, corresponding results are seen. (Table II.)

TABLE II.—Prof. E. H. Kettle: Table of Weights.

	Average weight in grammes.		Average gain or loss.	Percentage gain or loss.
	Before treatment.	After treatment.		
Diaplyte—				
10 guinea-pigs ..	445	394	-51	-11
Controls—				
10 guinea-pigs ..	394	424	+30	+ 8

Thus, in Kettle's series the controls are 19 per cent. better than the animals treated with diaplyte antigen. In my series the controls are 31 per cent. better than the animals treated with detoxicated vaccine and 26 per cent. better than the animals immunised with the bacillary emulsion.

¹ The Criteria of Cure in Tuberculosis of the Guinea-pig, THE LANCET, 1924, i., 68.

Microscopic Examination.—No microscopic examination was necessary in any of the animals that actually died from the disease, as the disease, seen by the naked eye, was in a very advanced state. Careful microscopic examination was made of the organs of all the animals that were killed on March 25th. It will be remembered that, although all these animals had palpable inguinal glands, their general health was apparently good. The lesions found in every animal, treated or control, were identical. The livers were the least affected, the lung next, while the lymphatic glands at and adjacent to the site of infection and the spleen were the most involved. Fibrosis was absent, and the pathological changes were of the proliferative cellular type. It may be safely said that the microscopic evidence points to the lesions being of recent origin, the infection having been localised to the seat of injection for a considerable period. Shortly before the animals were killed the infection had become systemic, and probably during the next four to eight weeks a steady loss of weight followed by death would have occurred.

A comparison of sections of organs of treated and untreated animals showed identical lesions.

Conclusions.

As judged by body-weight, the period of survival, and microscopic findings, tuberculin treatment of the experimentally infected guinea-pigs in this investigation was not only ineffective in controlling the infection, but was actually harmful.

ABNORMAL EXTERNAL JUGULAR VEIN.

By A. J. E. CAVE, M.B. MANCH.,

DEMONSTRATOR IN ANATOMY, UNIVERSITY OF LEEDS.

THE abnormality forming the subject of the present communication was observed recently in an adult male body during the course of its dissection in the anatomy department of Leeds University. It is deemed worthy of record partly because of its possible surgical significance, and partly because it does not appear to have been recorded previously.

Normal External Jugular Vein.

Normally the external jugular vein is formed by the confluence of the posterior auricular and posterior facial veins upon the superficial aspect of the sterno-mastoid muscle, at a point behind and below the angle of the mandible. The site of union is usually below the inferior limit of the parotid, but often the gland overlaps the origin of the great vessel, or the latter may commence actually in the parotid substance. From its origin the external jugular proceeds downwards and backwards upon the sterno-mastoid to the antero-inferior portion of the sub-clavian triangle, its surface marking being a line drawn from a point midway between the mastoid process and angle of mandible to about the middle of the clavicle. In its course it is covered by skin, superficial fascia, platysma, and, according to Poirier,⁸ the transverse branches of the cervical plexus (which, however, may pass deep to the vein); in the sub-clavian triangle it is deep to the suprascapular artery. Its posterior relations are the sterno-mastoid, the N. cutaneus colli, then (having left the sterno-mastoid about the junction of the middle and lower thirds of that muscle) the A. transversalis colli, the intermediate portion of omo-hyoid, the lower roots of brachial plexus, and the third part of the sub-clavian artery. To reach the sub-clavian vein the external jugular is obliged to perforate, first the superficial, and then the deep layer of the cervical fascia in the sub-clavian triangle, usually behind the clavicle; and as this deep fascia is intimately attached to the whole circumference of the vessel wall, the

lumen of the vein is maintained at a maximum. According to Struthers⁹ the valves of the external jugular are defective, and this fact, in conjunction with the inability of the vessel to collapse at its site of transit through the deep fascia, enhances the likelihood of air-embolism following wounds of the vein.

The more constant tributaries of the external jugular are (1) the posterior external jugular (entering at posterior border of sterno-mastoid); (2) the

Abnormal relations of external jugular vein. B.P.=Brachial plexus; O.H.=omo-hyoid; T.C.V.=transverse cervical vein; P.E.J.V.=posterior external jugular vein; Comm.V.=communication between E.J.V. and subclavian vein; S.=subclavian muscle; S.A.=suprascapular artery; Sc.A.=scalenus anticus; C.=communications from anterior jugular vein; E.J.V.=external jugular vein.

transverse cervical vein (above posterior belly of omo-hyoid); (3) communications from the common facial and anterior jugular veins (crossing the sterno-mastoid); (4) the anterior jugular itself (passing deep to sterno-mastoid); and (5) sometimes the suprascapular vein.

Recognised Abnormalities of External Jugular Vein.

It may be absent on one side, or on both, according to Cunningham,¹ Quain,² Piersol,⁴ and Morris.⁶ It may vary considerably in its mode of origin, being sometimes the continuation merely of the posterior facial vein, or the posterior auricular; in such cases it is small, the internal and anterior jugulars being enlarged. It may receive the lingual vein (Morris) and the cephalic vein (Quain, Morris), this being the persistence of an early developmental phase; and when the other jugulars are subnormal in size, the present vessel is proportionately enlarged. According to Morris⁶ it may pass over the clavicle to open into the cephalic, and both Quain² and Morris⁶ draw attention to its occasional jugulocephalic branch. Morris figures this branch on p. 648. The vessel may be double according to Gray³ and Piersol; Sobotta⁵ and Sappey⁷ make no comment upon such variation. One author⁴ states that the vein is sometimes pierced by the N. cutaneus colli.

Present Abnormality.

As shown in the drawing, this external jugular vein was normal at its origin and in its sterno-mastoid course. On leaving the superficial surface of that muscle it came to lie upon the roots of the brachial plexus, and the *A. transversalis colli*; but instead of crossing the omo-hyoid also it pierced the deep fascia just above the muscle, and passed *deep* to the intermediate portion thereof, sending off, however, a small vein which descended over the omo-hyoid to enter the subclavian. Thus the intermediate part of the omo-hyoid was enclosed in a venous loop, through which ran also the suprascapular artery, anterior (as normally) to the external jugular itself. As a result of this anomalous disposition the great vein was "tacked down" fairly deeply in the neck, and was also more tortuous in its lower part than the diagram suggests. The anomaly was bilateral; the anterior jugulars were very small; both internal jugulars were present and of normal size, but the external itself was fully thrice its average size.

I have no evidence as to whether, in life, the external jugulars were subjected to compression by the omo-hyoid; this would probably be obviated by the venous communications with the anterior jugulars and by the extra communicating vein present. Possibly, in development, the omo-hyoid split the lower part of the external jugular system; but that is a minor point.

Clinical Significance.

Note in connexion with this anomaly (a) its large size, (b) its passage deep to the omo-hyoid, and (c) its transit through the deep cervical fascia above the level of that muscle, the vein possessing, in consequence, an abnormally deep course in the subclavian triangle. Given a vessel so disposed, the surgeon working in the posterior triangle, upon the plane of the omo-hyoid, might, thinking himself in no danger of wounding the external jugular, proceed to a deeper plane. His next manoeuvre might then bring him unexpected and profuse hæmorrhage, and the grimmer catastrophe of air-embolism. Moreover, the superficial communicating vein lying over the omo-hyoid might easily be mistaken for a normally placed, though small, external jugular, and so still further mislead the operator. Apparently this variation is uncommon, but to guard against danger in case of its occurrence the surgeon might be advised to incise half an inch above the clavicle just anterior to the anterior border of the trapezius, then to dissect down and secure the posterior belly of the omo-hyoid, and by blunt dissection to follow this up to the intermediate portion, reflecting medially all tissues superficial to the muscle. In this manner the normally disposed external jugular would be retracted out of harm's way, and an abnormal, deeply-lying vessel would be exposed in time to avoid injury to it.

INTERNATIONAL CONGRESS FOR INDUSTRIAL ACCIDENTS AND PROFESSIONAL DISEASES.—At a meeting in Amsterdam on Dec. 21st last, the Permanent Committee of the International Congress for Industrial Accidents and Professional Diseases (*Ongeaccellengeneeskunde en Beroepsziekten*), which has not been in session since 1912, was reconstructed, Sir Thomas Oliver (England) and Dr. Kaufmann (Switzerland) being elected as hon. presidents. The fourth congress is to be held in Amsterdam on Sept. 7th, 1925. An English committee, under the presidency of Sir Thomas Oliver, is now being formed and the names of the members will be published later. Dr. H. S. N. Menko is hon. secretary of the English Committee, and his address is 2, Grosvenor-gardens, Cricklewood, London, N.W. 2.

TWO CASES OF ALARMING HÆMORRHAGE DUE TO STREPTOCOCCUS INFECTION.

By MACLEOD YEARSLEY, F.R.C.S. ENG.,

AURAL SURGEON TO THE LONDON COUNTY COUNCIL; CONSULTING
AURAL SURGEON TO THE ST. JAMES'S HOSPITAL, BALHAM.

THE following two cases, in which alarming hæmorrhage occurred as the result of the presence of a hæmolytic micro-organism, are both interesting and instructive:—

CASE 1.—Mr. A., aged 20, the subject of marked nasal obstruction (due to an accident some 18 months previously) and septic tonsils causing frequent sore throats, during which he was incapacitated for work, was operated upon in December, 1920. A submucous resection was performed, followed by dissection of the tonsils. Nasal plugs of compressed gauze were inserted in accordance with my usual method. A troublesome general oozing from the tonsils followed, which was treated at first in the usual manner. No special bleeding spot could be found, and it was noted that the hæmorrhage appeared to occur at about 20-minute intervals, each attack being heralded by the detachment of very friable clot, which broke up easily. Thirty grains of calcium lactate were given, with saline injections four-hourly. The bleeding became less, but at 10 P.M. recurred with renewed severity. The tonsils had been very septic, and I was loth to carry out a suggestion of suturing the faucial pillars. The patient was, therefore, seen in consultation by Dr. H. G. Butterfield, who remarked upon the strong streptococcus odour of the case. Twenty cubic centimetres of antistreptococcic serum were at once injected, and by 11.30 P.M. the bleeding had practically ceased. The next morning the patient was much better, but there was still a little oozing, and a second dose of 20 c.cm. of serum was given at 10 A.M. by Dr. Butterfield. At 12.30 P.M. there was only slightly blood-stained mucus, and by 5.30 P.M. all bleeding had ceased. The nasal plugs were removed at 10.30 A.M., without the occurrence of any hæmorrhage.

CASE 2.—Mr. B., aged 22, had suffered from colds, morning nausea and sickness, and repeated sore throats for some time. The tonsils were septic, and he showed the complexion and acneiform eruption of chronic toxæmia. The tonsils were dissected out in February, 1923, the left containing much foul-smelling, cheesy material. The patient did well until five days later, when there was a slight attack of hæmorrhage which yielded to treatment. This recurred next day at 5.30 P.M. more severely, and was treated by the injection of 1 c.cm. of hæmoplastin. The fauces were much swollen, with hæmorrhagic patches, and I noticed a strong streptococcic odour which had not been manifest before. The clot showed the same friable nature as in the previous case. Hæmorrhage recurred next day, and he was seen in consultation by Dr. Butterfield, who gave 25 c.cm. of antistreptococcic serum at 4 P.M. The effect was remarkable. By 6 P.M. the bleeding had entirely ceased, the swelling of the fauces had greatly diminished, and the unpleasant smell was much less noticeable. Further progress was uneventful. A swab, taken at the consultation, swarmed with streptococci.

Commentary.

Both these cases show much the same features. In both hæmorrhage was due to a hæmolytic organism, rendering the clot soft and liable to crumble at the slightest touch. In both the unpleasant, bad-meat odour, characteristic of streptococcus infection, was present. In the first case no swab was taken, so that the diagnosis was not confirmed bacteriologically, although there can be little doubt clinically as to the similarity of infection in the two patients. The effect of an antistreptococcic serum was quickly marked in both cases, especially in the second, and the rapidity with which the smell disappeared in this case was remarked by everybody, including the patient's relatives.

The futility of any other treatment in such cases is obvious. It was proposed to me in the first case to suture the faucial pillars. Had I done so, the removal of the stitches 24 hours later would have certainly been attended by renewed bleeding, and the effect of such an operation upon the septic tissues can easily be imagined.

A CASE OF EXTREME MALFORMATION OF THE UTERUS

ASSOCIATED WITH PERIODIC PAIN.

By FRANK COOK, B.Sc., M.B., B.S. LOND.,
F.R.C.S. ENG.,

OBSTETRIC AND GYNÆCOLOGICAL REGISTRAR, GUY'S HOSPITAL.

THE following case of uterine malformation seems to be worthy of record:—

A girl of healthy appearance, aged 17, was referred to me by Dr. John Hollings on account of primary amenorrhœa and intense periodic pain in the left lower abdomen, accompanied by vomiting. This pain recurred at regular intervals of 28 days, and lasted for three or four days on each occasion; it had started at the age of 13, and tended to increase in severity. Although the development of the breasts, vulva, and secondary sexual characters in general appeared to be perfectly normal, the vaginal canal and uterus were found on recto-abdominal examination under anæsthesia to be extremely ill-developed or entirely absent. The right ovary was distinctly palpable, the left seemed to be considerably enlarged.

Various forms of medical treatment were applied without avail. The girl was seriously incapacitated during the monthly attacks, and her doctor found considerable doses of morphia necessary to alleviate the pain. On account of this latter fact, and in view of the definite localisation of pain and apparent ovarian enlargement, it was decided to operate. Laparotomy revealed the following state of affairs.

The left ovary was normal in size and general appearance. The right ovary was considerably elongated, and about twice the size of that on the left; at its upper pole was a recently ruptured Graafian follicle. (In this latter connexion it should be noted that operation was performed

This was judged to represent a rudimentary uterus or adenomyoma, and it was consequently excised as the probable source of pain (Fig. 1). On section the excised

FIG. 1.

A, Bladder; BB, round ligaments; C, ovarian ligament; D, tumour representing rudimentary uterus; E, left ovary; F, right ovary; G, recently ruptured Graafian follicle; HH, Fallopian tubes.

tumour was found to consist of tough muscular tissue, of which the fibres appeared to be concentrically arranged. It was solid, apart from a minute circumscribed space at its centre. Examined microscopically by Dr. R. D. Passey, the bulk of the specimen proved to consist of plain muscle tissue, approximately disposed in three strata, of which the middle was the thickest and consisted of fibres arranged in various directions; the inner and outer layers contained fibres of mainly circular arrangement. The central cavity was lined by mucous membrane indistinguishable from

FIG. 2.

FIG. 3.

on August 6th, the last painful period having terminated on July 26th.) The abdominal ostia of both Fallopian tubes were normal in appearance, and patent. On the right side the tube was patent as far as a point near the internal abdominal ring, where it was closely attached to the round ligament; it thence turned as a narrow solid band to cross the posterior surface of the bladder and reach its fellow of the opposite side. Although the Mullerian ducts had thus met in the middle line, there was nothing whatever to indicate their further fusion or descent to the urogenital sinus. On the left side, and corresponding to the junction of the Mullerian duct and round ligament, there was situated a spherical tumour rather less than a golf ball in size.

uterine mucosa. In general, the examination indicated definitely that the tumour represented a rudimentary uterus developing abnormally in the course of the left Mullerian duct, and not an adenomyoma. Prof. A. Stokes kindly prepared the accompanying micro-photographs, which demonstrate in detail the structure in the neighbourhood of the central cavity. (Figs. 2 and 3.)

The patient has been entirely free from her periods of pain since the operation, although several months have elapsed. Unfortunately, in this particular case the causation of the pain has seemed so obvious as to throw but little light on the nature of dysmenorrhœa in general.

A NOTE ON THE ALLEGED DETERIORATION OF INSULIN IN THE TROPICS.

By A. NEAVE KINGSBURY, M.B., B.S., D.P.H.,
D.T.M. & H. LOND.,

PATHOLOGIST, INSTITUTE FOR MEDICAL RESEARCH, KUALA
LUMPUR, FEDERATED MALAY STATES.

DURING the past 12 months the deterioration of insulin in tropical climates has aroused considerable interest, if judged by the number of contributions on the subject which have appeared in the medical press. The majority of writers have expressed the opinion that there is a definite decrease in potency after insulin has been exposed to a tropical temperature for even a short time. Many of these workers, however, have based their conclusions on the blood-sugar findings from three or four rabbits only, and in their reports have laid insufficient stress on the probable error resulting from the small number of animals employed. The evidence now available that the reaction of rabbits to insulin in the tropics differs from that obtained in temperate climates also tends to discredit many results obtained in India and elsewhere.

But the careful work of Major Stott¹ on 12 diabetics in India is open to neither of these objections. He showed that a progressive fall in the potency of a large batch of insulin occurred month by month when

before the assay was commenced. During this period the average temperature in the building at 9 A.M. was 79.6° F., at noon 84°, and at 3 P.M. 83.5°, with corresponding maximum and minimum temperatures of 84.5° and 75°, 89° and 77°, and 89° and 76° respectively.

The strength of the insulin was 28 units per c.cm. when shipped from America, but to allow for decrease in activity doses of 0.075, 0.1, and 0.125 c.cm. per kilogramme were given to the three rabbits in series (1). As the third rabbit became convulsed, the dosage was decreased to 0.056, 0.075, and 0.094 c.cm. in series (2), (3), and (4). The insulin was diluted so that the doses could be accurately given, and injections were made subcutaneously into both flanks of each rabbit. The animals had been starved for 24 hours and blood-sugars were estimated before injection, and 1½, 3, and 5 hours afterwards.

Effect of Tropical Conditions on Carbohydrate Metabolism of Rabbits.

Applying the Toronto method of calculating unitage, the strength of the insulin, based on the results obtained from the first nine rabbits, shows a deterioration of about 40 per cent. after six months storage. Rabbits Nos. 10 to 12 (series 4) were the first local generation of Belgian hares imported from England some 11 months before, and they were given the same dosage per kilogramme as the rabbits in series (2) and (3) which had been purchased locally. None of these "local" rabbits became convulsed,

kept at room temperature. On first arrival in India this insulin was found to have a glucose equivalent of 12 g. per original unit, and the activity gradually decreased to a glucose equivalent of less than 1 g. per original unit after six months storage. If his monthly glucose equivalent values of the insulin are plotted against time, the resulting curve approximates to a logarithmic one. Further reference will later be made to this point.

On the other hand, Bose² has reported favourably on the keeping properties of insulin in India, and in January last a letter was addressed to the medical press by manufacturers of insulin³ stating that a batch had been kept at 95° F. for one month without deterioration, and that a voyage to India and back had been without effect on the activity of another batch. It must be admitted that this letter was not received without scepticism by many medical men in the East.

The writer has recently carried out a re-assay on a batch of American insulin which was received during the first week of April, 1924, and stored at room temperature in the laboratories here for six months

yet all three in series (4) went into convulsions and, although given intravenous glucose and adrenalin, rabbit No. 12 died.

The number of rabbits available was insufficient for a very accurate assay, and the weights of rabbits Nos. 1 to 9 were considerably below standard, but it is noteworthy that the insulin assay on "local" rabbits showed a fall in potency of about 40 per cent., while the assay on the first local generation of Belgian hares indicated that the insulin was practically as potent as when it was shipped. It may be urged that Belgian hares are perhaps more susceptible to the action of insulin than other rabbits, but the experience of Bose and Acton⁴ in Calcutta serves to negative this objection. These workers found that three original units of insulin per kilogramme weight caused a fall in blood-sugar of 45 to 50 per cent. in albino rabbits, and of 50 to 57 per cent. in Belgian hares, and that piebald rabbits were the most sensitive to insulin.

Climatic or dietetic conditions would therefore seem to modify the carbohydrate metabolism of the rabbit after many generations in the tropics so as to render it unsuitable for the standardisation of insulin, and

the writer hopes to confirm this observation by using successive generations of the strain of Belgian hares for insulin assay.

Factors Affecting Stability of Insulin.

Regarding the vexed question of the deterioration of insulin in the tropics, there is trustworthy evidence that some samples show considerable decrease in activity, while others retain their original potency for many months. We thus conclude that insulin may be stable at tropical temperature, but some batches are either impure or the character of the solution renders the preparation unstable. The logarithmic character of the curve obtained from Stott's results certainly shows that dissociation occurs in some batches. Insulin is known to be more stable in acid than in neutral solution, and Cheadle⁵ has demonstrated recently that it can be autoclaved at 125° C. for 20 minutes with a loss in activity of 20 to 25 per cent. only, if in solution of pH 2, but that it loses all activity if the procedure is carried out in solution of pH 4. The writer has noted that a batch which gave indifferent clinical results was less acid in reaction than a more active sample, so that the pH of the insulin solution may be a factor in the deterioration of insulin at tropical temperatures.

Summary.

A batch of insulin was stored for six months in the tropics and then reassayed on local rabbits. It appeared to have deteriorated by about 40 per cent. The reassay was also done on the first local generation of recently imported rabbits. The results then indicated little if any deterioration.

Clinical and Laboratory Notes.

THE DIAGNOSIS OF TUBERCULOUS MENINGITIS IN CHILDREN.

By W. L. KINNEAR, M.D. ST. AND.,

RESIDENT MEDICAL OFFICER, QUEEN'S HOSPITAL FOR CHILDREN,
BETHNAL GREEN, E.

TUBERCULOUS meningitis is not an uncommon disease in children, and accounted for 9 per cent. of deaths in the medical wards of this hospital in 1923. It is a disease which must cause much anxiety to practitioners owing to the difficulty of its diagnosis in the early stages. On the average patients were admitted well on in the third week when signs of advanced infection were usually present. The ease with which a certain diagnosis can be made in hospital has possibly led to less attention being paid to the signs and symptoms of onset; but lumbar puncture is not practicable for most general practitioners, and a diagnosis is often arrived at by the failure of the usual remedies and the appearance of grave cerebral symptoms.

I have felt that a general description of the signs and symptoms, as is found in most text-books, could be made more useful by a table showing their relative frequency; individually they are not distinctive, and it is only when in combination that they point to the diagnosis. There are certain points of much importance which must be omitted from this table, such as the facies, the alteration in behaviour in each patient, &c. The signs and symptoms given below were all present on or before admission, this being the stage of the disease when they were last

seen by the practitioner or when the mother brought her child to hospital for treatment. It is important to note that in this hospital the latter class is much the more numerous. No signs or symptoms developing in hospital are given.

I should like to comment on one point only, and that is on the asymmetry of distribution of the nervous symptoms. On looking over the notes I was much struck by the frequency of such signs as paralysis, twitching, spasticity, &c., confined to one limb or to one side of the body; the presence of Babinski's or Kernig's sign, abdominal reflexes, or knee-jerks on one side only. The temperature charts are frequently very suggestive of this trouble—an irregular, moderately raised temperature, a varying pulse-rate, and a persistent blank in spite of medicines in the column devoted to registering stools being the distinctive features.

Analysis of 100 Cases.

Lumbar puncture was done in 95 per cent.; post-mortem examination was done in 42 per cent. The average duration of illness from the first definite symptom—e.g., vomiting or convulsion—was 19.9 days. The average number of days in hospital was 8.2. The number of cases admitted when delirious or unconscious was 16. Forty-four were males and 56 females. A tuberculous family history was present in 34 per cent.

The age distribution was as follows:—

	Per cent.		Per cent.
0-1 years	18	4-5 years	12
1-2 "	24	5-10 "	10
2-3 "	18	10-14 "	7
3-4 "	11		

The youngest patient was 3 months old; the oldest patient was 13 years 8 months old.

Seasonal Incidence.—64 per cent. of the cases occurred during the first six months. The largest number occurred in March, when 22 cases were admitted.

The symptoms and signs were as follows:—

	Per cent. of cases.		Per cent. of cases.
Vomiting occurred in	89	Babinski's sign present in	31*
Constipation occurred in	81	Screaming occurred in	29
Headache occurred in	80*	Convulsions occurred in	29
Strabismus occurred in	31	Knee-jerks absent in	27
Stiffness of neck present in	65	Abdominal reflexes	
Kernig's sign present in	51†	absent in	20
Head retraction present in	35	Twitchings occurred in	15
* Over 2 years of age.		† Doubtful in six.	

Temperature.—The average temperature on admission was 99.8° F. Three cases showed no rise of temperature to 100° throughout. In ten cases the temperature rose over 105°. This was usually due to the ante-mortem elevation.

Examination of Cerebro-Spinal Fluid.—In nearly every case the fluid was under increased pressure, and a coagulum formed on standing.

Average number of cells per c.mm.	73.0
" percentage of lymphocytes	88.0
" " chlorides	0.675

An interesting point was the diagnostic importance of increased globulin content, a definite cloud with the Noguchi reaction being sufficient to exclude cases of meningism in which the fluid was also usually under increased pressure.

A CASE OF INTESTINAL OBSTRUCTION.

By A. GRAHAM BRYCE, F.R.C.S. ENG.,

ASSISTANT RESIDENT SURGICAL OFFICER, MANCHESTER
ROYAL INFIRMARY.

THE following case, from the unusual nature of the cause of obstruction, seems worthy of record:—

A married woman, aged 52, was admitted to the Manchester Royal Infirmary on March 8th with the following history. On Jan. 1st, 1924, she was suddenly attacked by abdominal colic and vomiting. The attack lasted for a week. Similar pain lasting for an hour had been present a fortnight before her admission. Thirty-six hours before being brought in she was again attacked by intermittent colic referred to the umbilical area. She had vomited several times during that period, but the vomiting did not become feculent. The bowels had been opened three times normally since the onset. Except for the presence of some tenderness at and around the umbilicus and shifting dullness in the flanks,

examination of the abdomen, hernial sites, rectum, and knee-jerks showed nothing abnormal. The temperature was 99.6 °F., and the pulse-rate 100. A diagnosis of incomplete intestinal obstruction was made, and the patient was kept under observation for about two hours, but, owing to the severe and continuous nature of the colic, it was decided to operate.

At operation a fair amount of free serous fluid escaped. The cæcum was collapsed, and no greatly distended gut presented, but three irregular hard bodies were found lying close together within the lumen of the small intestine at a point estimated to be three or four feet from the ileo-cæcal junction. The intestine below the site of impaction was collapsed. The foreign bodies were removed through an opening in the bowel wall, which was immediately sutured and the abdomen was closed without drainage. Recovery was uneventful.

The foreign bodies were examined after removal. They were found to be chestnuts, of which the largest was of the usual size and the smallest half the size of an ordinary chestnut. All were minus the outer shell and covered by a thin layer of faecal material. Inquiry elicited the fact that the patient had eaten roasted chestnuts on New Year's Day and had swallowed them whole. The interest of the case lies largely in the fact that the chestnuts had been quite unaffected by the digestive ferments over a period of nearly ten weeks.

I am able to publish this note by the courtesy of Mr. J. Howson Ray, to whose surgical unit the patient was admitted.

Medical Societies.

ROYAL MEDICO-CHIRURGICAL SOCIETY OF GLASGOW.

At two recent consecutive meetings of this Society Prof. ARCHIBALD YOUNG, the President, in the chair, a discussion was held on

Rheumatoid Arthritis.

Prof. R. STOCKMAN, opening the discussion, described the condition termed rheumatoid arthritis as most probably a group of closely allied germ diseases known and described under many different names—e.g., chronic articular rheumatism, chronic rheumatic arthritis, chronic fibrous rheumatism, chronic villous polyarthritis, nodose rheumatism, rheumatic gout, atrophic arthritis, Still's disease, chronic infectious arthritis, and so forth. The clinical course and morbid anatomy marked it as a germ disease of low virulence, but of extreme chronicity. As a rule, no organism could be found in the joints or other affected structures or in the blood, but in a certain number of cases (relatively a very small number) bacilli, diplobacilli, cocci, diplococci, and streptococci had been isolated from the joints and cultured outside the body. The probability was, he said, that there were several different causal organisms, but whether all cases were due to the same organism, or to various different organisms, the broad results for the patient were the same. The white fibrous tissues of the locomotory system of the body formed the point of attack, and essentially and in the beginning it was a fibrositis, with proliferation and increase of the affected fibrous tissue structures. There was never suppuration, and no local emigration of polymorphous leucocytes took place. Chronic hydrarthrosis of one joint was probably its mildest form, and from this there were all grades of severity up to polyarthritis with high fever. It usually began insidiously, the speaker said, in the small joints and progressed with little constitutional disturbance; much seldomer it began in the large joints, and then with more acute systemic symptoms. Ultimately in all cases it presented the general clinical aspect of a low chronic septic infection, and must be regarded as a very general infection, not merely as an arthritis. In all cases the fibrous tissue of the muscle, aponeuroses, fasciæ, and panniculus adiposus

were more or less deeply involved and inflamed. In the joints it was the fibrous tissue of the synovial membrane and capsule which were primarily affected. The cartilage and bone were not primarily involved, but as the influence of disuse, muscular contractures, and other changes came into play, the bone got thinned and atrophied, the cartilage became rough or ulcerated, the fibrous capsule contracted and hardened, and ultimately a fibrous or a bony ankylosis might result.

With regard to the search for a focus of infection, it was remarked how very infrequently any focus could be identified with certainty. It was possible that in many cases the original focus had disappeared before the patient came under observation; and a joint might remain as a reservoir of infection after others had ceased to show active signs. Tonsillitis, boils, septic sores, pyorrhœa, chronic pulmonary or intestinal conditions, and so on, had been blamed, and the association of various skin conditions, such as psoriasis, had been noted.

Treatment.

The various methods of treatment, both local and general, were then described. The later symptoms and changes which followed as a result of the fibrositis were referred to, and the necessity for vigorous treatment by massage, movements, baths, and appropriate exercises was urged—anything rather than rest. Treatment must be directed (1) to restore movement in the joints by elongating the contracted muscles and shortening the elongated ones, so that they may each regain their normal action; (2) to get rid of the fibrositis in and around the joints and to stretch and render more pliable their ligamentous tissues and adhesions; and (3) to bring up the bulk and strength of the muscles. For the most part the stretching and movements could be done manually, but the assistance of splints was desirable in many cases. Forcible extension under an anæsthetic was to be avoided, but in certain instances the mobility of a joint could be more easily tested under chloroform. The fixation of a joint in plaster or splints for more than a few days was very inadvisable owing to the risk of immobility occurring.

Dr. DAVID CAMPBELL described the results of the treatment of rheumatoid arthritis by non-specific therapy—the so-called protein shock treatment. He described the technique which he had employed in 100 cases from 1921 to the present date, and showed various charts illustrating the general and local reactions following the injection. Of 70 cases treated up to November, 1923, 58 derived great benefit, both directly from diminution of pain and tenderness in the joints, and also indirectly from the consequent greater facility with which more effective local treatment by heat and massage could be carried out. The maximum benefit was obtained in those cases which had started acutely and with involvement of many joints. Of the 12 cases which showed no improvement, four were of long standing in which the disease process had become inactive. Seven reacted to each injection, but the infection remained active. Of the 58 cases improved by the treatment, 40 had, from periods varying from one to three and a half years, been able to perform all their ordinary duties, with no exacerbation of the joint conditions nor spread of the disease to other joints. In 16 cases in which relapse had taken place, a fairly advanced stage of the disease had been reached before treatment was started, while in several the treatment had been discontinued after two or three injections, owing to the great improvement shown. The advisability was discussed of continuing the injections after the active process had apparently ceased. In conclusion, the opinion was expressed that, while protein shock therapy could not be regarded as ideal, it offered greater probability of success than any other known methods.

Prof. STOCKMAN was of the opinion that protein shock therapy was capable of cutting short the infection in the early stages of the disease.

Prevention of Deformity.

MR. JAMES RUSSELL, in discussing the surgical treatment of arthritic conditions, referred to the various deformities which might result from these diseases. He deprecated strongly operative treatment based on X ray appearances alone, and insisted that surgical interference could be justified only where improved functional value of the limb was likely thereby to be attained. The fundamental question was function, and mere deformity as such should not be allowed to assume undue importance. The commoner deformities of the various joints were then described and the methods employed for their prevention discussed. A number of splints were shown and the method of their use demonstrated. It was pointed out that the splints should be of such a type that they could easily be removed for massage and other local treatment. In the acute stage of the disease there was a limit to the patient's tolerance of treatment, and in such cases the skill and judgment of the surgeon might be taxed to the utmost. Once deformity had developed, any forcible movement was sure to be harmful, but gradual stretching by weights or splints could overcome many of these early contractures. In conclusion, Mr. Russell urged the necessity of physicians and surgeons appreciating the value of posture, during the acute stage of the illness, and splintage, in the prevention and control of deformity.

Discussion.

In the discussion which followed, Dr. W. S. SYME referred to the difficulty of finding a focus of infection, and urged that the examination of the throat and nose for any such focus should be more strict than was commonly the case. For example, it was often the most innocent-looking tonsil which showed the greatest degree of infection in the crypts when a thorough examination was made by pressing forwards the pillars and projecting the tonsil towards the observer. In the case of nasal infection, even more care was required to demonstrate the freedom from infection of the various sinuses. In some cases where generalised infection had occurred, removal of the primary focus did not afford relief, probably because secondary foci were then equally fertile as sources of infection.

Dr. J. N. CRICKSHANK referred to the occasional occurrence of herpes after protein shock therapy. He quoted six cases in which severe herpes of the mouth and lips and surrounding area of skin had occurred. Subsequent injection of a fresh vaccine from the same stock was again followed by herpes. One patient had been treated by a vaccine from a different stock without the appearance of herpes. When treated by the vaccine which produced herpes in the other patients, he also suffered in the same way. These facts suggested the need for care in selecting a suitable stock vaccine.

Dr. MARION GILCHRIST spoke of the difficulties in the treatment of rheumatoid arthritis and of the problem of individual resistance to such infections. The vigorous application of all measures calculated to raise the patient's general resistance was essential. In the prevention of deformities and limited function, movement was important. Pain was a difficult symptom to treat, and in several instances she had found local X ray treatment of much benefit in the relief of pain. She wished particularly to emphasise the importance of treating the mental attitude of the patient. It was essential to increase the mental resistance of the patient to the disease.

Dr. G. H. CLARK referred to a point of interest in the treatment of resistant cases by heat. He had found that a dressing of methyl salicylate and carbolic oil along with the application of heat gave in some cases a much better effect than heat alone. He had also found better results in some cases with the Grevillite bath than with ordinary radiant heat.

Reviews and Notices of Books.

FRANCIS GALTON.

The Life, Letters, and Labours of Francis Galton. By KARL PEARSON. Vol. II. Cambridge University Press. 1924. With 54 plates and many taxy figures. Pp. 425. 45s.

THE first volume of this biography was published in 1914; we have waited ten years for this, the second instalment; the third has yet to appear. And in the meantime circumstances have led to some alteration in its scope and method. In the happy days of pre-war printing ventures, the Galton professor had contemplated an issue of Galton's collected works, particularly desirable in the case of an author who dispersed a great amount of noticeable work among a variety of journals and magazines as well as writing his more formal books and scientific papers. This project has, we are sorry to read, perforce been given up. Instead, and as far as may be in substitution, the biography now gives a fuller account of his writings, summarising them in enough detail to enable the reader to apprehend what Galton did and, in the light of Prof. Pearson's comments, to appreciate what his doings stood for when they were done and what they stand for to-day. As far as the biography is concerned, this change is for the better. It involves, it is true, the expansion of the whole from two to three volumes, and the third is still unpublished. But it has led to an account of the life and work of a scientific man which is without parallel in recent English biography, and reaches a pitch of excellence of which it is difficult to speak without exaggeration; it was reached before by Prof. Pearson in his account of W. F. R. Weldon in the fifth volume of *Bio metrika*, and the present volume alone of Galton's life is about ten times as long as that memoir.

If Galton had been a man of one idea or even of one recognised field of inquiry, if his own "Memories of My Life" had been something more than trivial (for they are hardly better than that), his biographer's task might have been relatively simple. Among his great contemporaries whose lives are classics, Darwin is evolution, J. D. Hooker is the Himalaya and Kew, even Huxley might almost be said to have lived in a groove. But anything which his amazingly curious mind happened to notice was a subject for investigation by Galton, and he had to an exceptional degree the habit of noticing things which other people had missed. Between many of his interests there was, of course, a nexus of relationship or development, but just as he was continually striking out as a pioneer into fresh topics, so he invented the idea that nearly all these interests were parts of a connected whole. This whole has no clear name; it is not anthropology in the ordinarily accepted sense, it is not eugenics as that term is commonly understood. We doubt whether more than a few people have been in a position to know what its content was before Prof. Pearson gave us this biography, and it is difficult to think of a more appropriate name than Galtonism.

The first volume was largely preparatory and brought Galton to the age of 32, an experienced traveller in foreign parts, married and prepared to settle to a quieter life. This second instalment tells us of his really effective middle life and develops the versatility of a mind which must surely have been one of the most genuinely original of last century. He writes the "Art of Travel," a standard book, which went through many editions, of recipes for camping, avoiding sore feet, dodging wild animals, and rolling up your shirt sleeves (which last is either quite wrong or applies to a kind of shirt not now in common use); is active at the Geographical Society; notices that very little attempt is made by meteorologists to get general rules out of their laborious data, discovers and names the "anticyclone," and on April 1st, 1875, procures the publication in the *Times* of the first of our familiar daily weather maps;

looks into spiritualistic phenomena; suggests a method of achieving a decimal system of coinage. These are a few of the items of his activity dealt with in the first chapter. We pass, then, to "Hereditary Genius" (published in 1869) and all the studies cognate to it which henceforward tend more definitely to group themselves round the study of the heredity of the mental and moral characters as a basis for race improvement and which centre in his three other fundamental books—"English Men of Science, Their Nature and Nurture" (1874), "Human Faculty" (1883), and "Natural Inheritance" (1889). There are interesting and less familiar experiments on the influence of blood transfusion and experimental Siamese twinning on heredity, undertaken with immediate reference to his cousin's hypothesis of pangenesis; composite photography; anthropometry and some correspondence with Florence Nightingale about a proposed professorship of applied statistics. Only cursory mention of some of the activities of these crowded years is possible. And Prof. Pearson, with his commentary and explanations, at once human and erudite, has woven it all into a tale which is of rare fascination in itself and has the truly Galtonian quality of suggesting how and where we may make further progress and help to run down some of the many hares that Galton started. Our gratitude to Prof. Pearson will be even greater if he will quickly produce the final volume which will deal with statistical heredity, correlation, fingerprints, and the rest of his subject's later work.

INTERNAL DISEASES.

The George Blumer Edition of Billings-Forchheimer's Therapeutics of Internal Diseases. Edited by GEORGE BLUMER, M.A. Yale. M.D., David P. Smith Clinical Professor of Medicine, Yale University School of Medicine, Attending Physician to the New Haven Hospital. New York: D. Appleton and Company. 1924. With illustrations. In six volumes and an Index volume. Pp. 4834. £12 the set.

WHEN the practice of medicine first separated itself from the priestly vestments which clothed it in its early youth, men were wont to speak of the healing "art." With modern rationalism has come a tendency to regard this phrase as inapplicable to medicine, and to try to confine therapeutics to the administration of remedies for which a scientific basis of action can be discovered. So long as effective empirical methods are not scorned simply because we do not at present understand them, the efforts to explain their action can only lead to good. It is to America particularly that we have come to look for such efforts, and the volumes before us represent an attempt by more than 150 authors to deal with all the diseases which afflict the internal organs of man from the point of view of pathology, sociology, and treatment, leaving symptomatology and diagnosis almost out of consideration.

The first volume of this large series is entitled "Principles of General Therapy," and opens with a general account of the cell and its physiology as the rational basis of all therapeutics. From a disquisition on such general subjects as colloids, equilibrium, diffusion, ions, osmosis, &c., the reader passes on to a chapter on feeding, wherein he will find some helpful and elaborate diet tables and estimates of food values, of the digestibility of the various articles of diet, and of the effect of cooking on them. The chapters which follow give an outline of modern methods of hydrotherapy, exercise, light and radiation applications, and kindred subjects. The chapter on organotherapy deals with this vexed subject in a moderate and conservative manner. The second volume continues the general principles with a sensible article on psychotherapy as it comes within the province of the practitioner, and with chapters on immunity, anaphylaxis, and blood. The various methods of administering remedial measures are then considered, and the "special" division of the work opens with

the infectious diseases. Tuberculosis and the pneumonias occupy the larger number of pages in this volume. The third volume deals with infectious diseases due to filter-passing viruses, under which heading are grouped—perhaps a little prematurely—acute arthritis and all the exanthemata. The mycoses, protozoal and metazoal infections follow. "The Intoxications" is the heading of the next group, in the course of which poisoning from all sources is considered, including food preservatives and belligerent gases. In the concluding chapters the subject of seasickness is treated with an appropriate breeziness. Rhinologists and psychotherapists will, perhaps, feel somewhat aggrieved at the exclusively anaphylactic treatment recommended for hay fever and asthma in Vol. IV. The deficiency diseases, ductless glands, vasomotor and metabolic diseases are dealt with in subsequent chapters, and the alimentary canal is then taken systematically, followed by diseases of the blood and lymph systems. The fifth volume treats of the thoracic organs, blood-vessels, and skeletal and excretory system and of occupational and tropical diseases. The concluding chapter gives a comprehensive survey of the various poisonous animals and plants and the treatment suitable to each. The final volume deals with the sexual system in both sexes, the nervous system, and eye and ear.

It will be seen that the range of the work is very extensive, but the treatment of each subject is by no means sketchy, such important practical details as diet tables, regimen of life, and suitable prescriptions being provided in every section. The bibliographical reference lists at the end of each chapter are full, and the reader who wants to pursue investigations further than the text takes him, or who wishes to trace recommendations to their source, will find no difficulty in so doing. The discussion of transmissible diseases and others having a social significance is characterised by a sympathetic and common-sense recognition of the personal problems of the patient as well as of the duty of physician and patient to the community. As will be seen from the summary of contents given, there is some overlapping and duplication, inevitable perhaps in a production for which so many writers are responsible, and the order of classification is one not wholly familiar to English readers, though based on rational principles. The indexing should serve to overcome this difficulty; each volume is fully indexed and a Composite Index to the entire work is bound separately for desk use. The volumes are disappointingly heavy in these days of light paper, but inasmuch as the work is essentially one for reference rather than steady perusal, this disadvantage is less important.

Novelty medical men will find here a refreshing novelty of presentation of well-known treatments, and some new suggestions of real value.

CLINICAL METHODS.

A Guide to the Practical Study of Medicine. Eighth edition. By ROBERT HUTCHISON, M.D., F.R.C.P., Physician to the London Hospital; Physician to the Hospital for Sick Children, Great Ormond-street; and HARRY RAINY, M.D., F.R.C.P. Edin., F.R.S.E., formerly Physician to the Royal Infirmary, Edinburgh. London: Cassell and Company, Ltd. 1924. Pp. 688. 12s. 6d.

THE new edition of "Hutchison and Rainy" has been revised by Dr. Robert Hutchison with the help of Dr. Donald Hunter, Dr. J. R. Marrack, Dr. P. N. Panton, Dr. John Parkinson, and Dr. George Riddoch. In 646 pages of text and some 40 pages of index are to be found the most remarkable summary extant of all that is best as regards the examination of patients. This is one of the books that may well stand as a proof of the high status of British medicine, and the reader puts it down with a feeling of gratitude to its distinguished authors, one of whom is unhappily no longer with us to enjoy its success. Complicated biochemical processes such as blood analysis are fully described,

but are relegated to positions which bring out their true relation to less "modern" but even more important methods such as the routine examination of the various systems of the body. On p. 253, "sulphanilic acid 1 c.c." should read "1 gram," a misprint which is reproduced from the original paper quoted on the same page; beyond this small error, we have found no mistakes in the descriptions of various complicated processes.

We hesitate to suggest that so trusted a servant should change his livery, but we feel that, when a book is of the excellence of the present one, a somewhat larger page would enable it to assume a form at once more dignified and useful.

MATERIA MEDICA.

A Text-Book of Materia Medica. Being an Account of the More Important Crude Drugs of Vegetable and Animal Origin. Designed for Students of Pharmacy and Medicine. Fourth edition. By HENRY G. GREENISH, D.-ès-Sc., F.I.C., F.L.S., Professor of Pharmaceutics to the Pharmaceutical Society of Great Britain and in the University of London. London: J. and A. Churchill. 1924. Pp. 586. 25s.

THE term materia medica has changed its meaning gradually in the last 40 years. The term as used in this book corresponds to the modern use of the word; it gives the source and descriptions of the plants and plant-derivatives which are used in medicine. "Greenish" is a book primarily for the pharmacist; but there must even now be many physicians who do take an interest in their drugs, and for these it can only be a source of delight.

He is a clever writer who can make interesting a text-book on the source and structure of drugs, but Greenish, partly by the simplicity of his style and partly by the clever use he makes of his illustrations, arrives at success. A look at the well-chosen pictures gives confidence, and a search into the text confirms this confidence. No words are wasted: the writer has a task to carry out and he does it without much ado. We can recommend the book to all pharmacy students and to those medical men who want to know more of their drugs than that they come out of a chemist's shop and that they can be obtained by writing a prescription.

INFECTIOUS DISEASES.

Diagnosis and Treatment of the Infectious Diseases. By FREDERIC H. THOMSON, M.B., C.M. Aberd., D.P.H. London: H. K. Lewis and Co., Ltd. 1924. Pp. viii.-208. 7s. 6d.

Dr. Thomson's valuable work in connexion with many of the infectious diseases is well known, and the publication in this volume of his post-graduate lectures will receive a wide welcome. The book is admirably suited for the busy general practitioner, containing as it does in compact form all that is material regarding the differential diagnosis and treatment of the infectious diseases liable to be met with in this country. At the same time it will prove of great interest to those whose work lies in fever hospitals and who are desirous of comparing their own methods with those of one whose prolonged experience commands respect. A short chapter, full of useful information, on the conveyance of infection opens the volume, and the possibilities of transmission of droplet infection by the air are briefly discussed, conclusions being drawn from the results of the author's experiments with "bed isolation" methods of nursing. It is interesting to note his belief that in measles the infectivity of the patient ceases with the disappearance of the rash and that in chicken-pox probably does not outlast the first week of the eruption, or in mumps the subsidence of the swelling. Dr. Thomson is more cautious regarding whooping-cough, and contents himself with saying that infection has gone when the patient ceases to whoop, whereas many hold that there is very little risk when once the paroxysmal stage has fully developed.

The chapters on the individual diseases are all good, those on small-pox, chicken-pox, and diphtheria particularly so. Many hospitals have discarded all local treatment of the throat in diphtheria, but it will cause surprise to learn that even in septic scarlet fever the same course is recommended. That much unnecessary exhaustion has been induced by persisting with local treatment must be admitted, and it is reassuring to hear that Dr. Thomson considers that the patients do quite as well without the traditional swabbing or douching of the throat. Throughout the book the author's suggestions for treatment seem eminently sound and sensible. An excellent section is that on tracheotomy. The few plates, chiefly illustrating small-pox and chicken-pox, are admirably chosen, and the book is clearly written and well printed.

THE SCIENCE AND ART OF LIVING.

By LEONARD WILLIAMS, M.D. London: Hodder and Stoughton. 1924. Pp. 240. 5s.

Dr. Williams's little book is didactic and propagandist, to use his own words, but the teaching and the advocacy are very entertaining. They centre round the author's belief that the crime of our civilisation is gluttony, begotten of an arrogant assumption of superiority. To eat, whether you want to or not, because it is one o'clock, is to the author one of the most fantastic acts of physiological folly that can well be perpetrated. Only if the bowel is supplied with plenty of vitamins does it empty itself automatically and generously; and the cooking-stove to the author is one of man's most deadly inventions, deadlier than the spirit-still, and only to be classed with the closed window. Round this thesis it would be easy—it has, in fact, been done—to write a very dull book, but Dr. Williams castigates others with good humour. He scoffs at the little luxuries to which man has accustomed himself "to keep up his strength," "to pull him together," "to neutralise acid," and so forth. Any suggestions to the contrary, to the effect that no such reinforcements are needed, sends the subject off to the miracle-monger, for he does not know what Dr. Williams knows, that man is, in fact, at any given moment, a resultant of his endocrine hormones.

So much for the science of living. Part II., on the art of living, contains much sound advice for local hygienic precautions. It is not, the author thinks, the pressure of the hat that causes baldness, but the harbouring of dirt; for a man will wear the same hat month after month, perspire in it, leave it about in all manner of odd places, without more than a perfunctory superficial external brushing. Who desires to retain a crop of hair should wash the inside leather band with soap and water at least once a week. The town-dweller should cleanse the inside of his nostrils morning and night with soap and water, adding some volatile antiseptic oil during a time of epidemic. He should avoid all the sticky foods represented by starches and sugars, all concentrated foods (beef-tea, Dr. Williams remarks, is more an excrementitious substance than a food), he should avoid misinterpreting as hunger the sinking feeling in the pit of the stomach, when it is really a form of indigestion for which the proper treatment is not tea but muscular exercise. An occasional three-day fast is enjoined in order to use up the material unwittingly put by the body for a rainy day, but the fast to be beneficial has to be cheerful and devoid of self-pity. The hungry reader will be relieved to find that after observing all the author's maxims, an evening meal will still remain for him consisting of fish and a salad, bird with a green vegetable, toast, cheese and fruit, varied with some of the etceteras such as chicken's liver and cod's roe—for the rational diet is in no sense synonymous with starvation diet.

Dr. Williams desires to rouse his readers from intellectual lethargy in matters scientific, and induce them to revise their standards and uplift their ideals. His attempt is stimulating and piquant.

PEDIATRICS.

Clinique médicale des enfants: Affections de l'appareil respiratoire. By Prof. P. NOBÉCOURT. Paris: Masson et Cie. 1924. Pp. 348. Fr.22.

THE attempt to teach clinical medicine by writing a book always seems a little paradoxical, but Prof. Nobécourt has succeeded in bringing the physician as close to the bedside as the written word will permit. As he says in the preface, his aim has been to paint complete pictures without any unnecessary detail, to convey clear-cut impressions and to ignore all that is hazy and uncertain. Much of this book deals with case-reports, but they are not like the ill-assorted clinical notes sometimes used as padding when the sources of inspiration run dry. Prof. Nobécourt's case-reports are strictly pruned, and he has the rare gift of describing a case in words that vividly conjure up a mental picture. Those of his readers who have enjoyed the privilege of listening to Sir Clifford Allbutt's bedside demonstrations will be reminded thereof when they take up this book. Passing from generalities to the special case, and back again to generalities, the author attaches one to the other in the way best calculated to leave a permanent impression on the reader's memory. With the atmosphere of the sick-room rather than the library, the author is as justified as anyone can be in calling this a clinical treatise. The sub-title—*Affections de l'appareil respiratoire*—gives the best summary possible of the contents of this volume.

REMINISCENCES OF AN OLD PHYSICIAN.

By ROBERT BELL, M.D., F.R.F.P.S. London: John Murray. 1924. Pp. 291. 16s.

Dr. Bell is well known as an earnest advocate of the treatment of cancer without operation. The main part of his book, however, deals with his life in general apart from purely professional work, early education, fishing excursions, travels, views on art and architecture, poetical compositions *et hoc genus omne*. Though a Scot, he was born in Alnwick, studied at Glasgow, and practised at first in that city and also in Durham. In 1893 he married and went for a continental honeymoon. Among other places he went to Florence, concerning which place he says, "it does not seem to be generally known that the real and original Chartreuse Monastery—for it is the oldest edifice of the order—is situated within a short carriage drive from Florence." It certainly is not generally known; it is not even the fact. The real and original Chartreuse Monastery is not far from Grenoble, where St. Bruno founded his order in 1086, though it is true that the existing buildings mostly date from the seventeenth century. Dr. Bell was evidently much struck by the cleverness of the Florentine school of copyists, and tells us that he purchased a copy of a picture by Carlo Dolce, a strange choice in a town which is full of works by Botticelli, Gentile da Fabriano, Filippo Lippi, and Ghirlandajo, to mention only a few. Dr. Bell also purchased a copy of a picture in the Monastery of St. Marco by a painter whom he calls Fra Angelica. The only thing that he tells us about his stay in Venice is how he successfully treated a gentleman from Leeds who suffered from constipation with a dose of castor oil. In Milan, though it is true that he considers that Leonardo's "Last Supper" "still held its position as a masterpiece," he apparently missed the chief thing to notice in the Duomo, the two *ambones*, and was struck chiefly by the modern glass and the imitation of groining on the roof. Dr. Bell's artistic tastes, however, improved, for in 1902, on his visit to Spain, he greatly and properly appreciated the Alhambra and Toledo Cathedral. In the same year Dr. Bell published an "In Memoriam" upon Queen Victoria, which he gives in extenso and which might have been written by the Rev. Robert Montgomery. Lest we shall be accused of doing nothing but cavil, we express our hearty thanks to

Dr. Bell for the following reminiscence (v. p. 236). He was one day walking down Sauchiehall-street in Glasgow, when he was accosted by an inebriated person, who "addressed me as follows: 'W-will yo-you p-please to tell me wh-which is the o-other si-side of the street?' I replied, pointing across the way 'Over there, of course.' Whereupon he said, 'Do-on't try to ga-ga-gammon me, for I was o-o-over th-ther and a ma-ma-man t-t-told me it was over here.'"

INSANITY AND LAW.

A Treatise on Forensic Psychiatry. By H. DOUGLAS SINGER, M.D., M.R.C.P. Lond., and WILLIAM A. KROHN, A.M., M.D., Ph.D. Philadelphia: P. Blakiston's Son and Co. 1924. Pp. 437.

ONE of the objects in the publication of this book is to bring about a better understanding between the medical and legal professions in matters of lunacy. It may be considered in two parts, of which the first is a text-book of psychiatry for the lawyer, and the second a law manual for the physician. The latter section deals, of course, with procedure in the disposal of the insane, criminal responsibility, testamentary capacity, and a great variety of other medico-legal problems which insanity may present. There is an excellent chapter entitled "The Physician in Court." The book will no doubt serve a useful purpose in America, but its value in England is limited by differences between the lunacy laws of the two countries.

ANNALS OF ROENTGENOLOGY.

Vol. IV. Normal Bones and Joints Roentgenologically Considered. By ISIDORE COHN, M.D., F.A.C.S., New Orleans. New York: Paul B. Hoeber. 1924. With 220 radiograms. Pp. 218. \$10.

THE series of monographic atlases grouped under the title of Annals of Roentgenology is edited by James T. Cast, an ex-president of the American Roentgen Ray Society. This volume is the last published, but six others are in actual preparation and others are being planned. It is to be hoped that nothing will hinder the early publication of those already in hand, and that those planned will embrace the whole of the wide field of roentgenology. This volume is a study of the appearance of normal bones and joints, and is a wonderful pictorial record of the changes which occur as a child grows into adult life. The extraordinary care which has been taken is well illustrated by the section on the elbow-joint, for the following radiographs are shown: at 17 months, 1; 5 years, 3; 6 years, 2; 7 years, 1; 8 years, 4; 9 years, 3; 10 years, 2; 11 years, 5; 12 years, 6; 13 years, 8; 14 years, 3; 15 years, 3; 17 years, 3. These 44 plates are all of normal joints, and there follow 15 plates illustrating the architecture of the joints with regard to normal angles, and lastly 30 photographs of fractures and the patients concerned before and after treatment. All the other joints are treated in a similar manner. The author explains in the text the details of ossification, of the structure and architecture of the joints, and presents the whole in a most attractive way. Later his points are emphasised by various fractures, and the case-histories of his patients are given in full. It is, of course, impossible to have even the smallest knowledge of abnormalities until the normal appearances are thoroughly understood. This monograph presents this aspect in the fullest possible manner, and meets an urgent need in the literature of bone and joint surgery. In the announcement in front of this volume we see no promise of a volume devoted to the pathological conditions of bones and joints, and we hope that this series will not be considered complete until such a volume has been written.

The Conduct of Medical Practice.

A Series of Articles by Experts dealing with the Difficulties Encountered in Professional Life and How to Meet Them.

XXIV.—DOCTOR AND CORONER.

BY G. ROCHE LYNCH, O.B.E., M.B.,
B.S. LOND., D.P.H.,

OFFICIAL ANALYST TO THE HOME OFFICE; PATHOLOGICAL
CHEMIST TO ST. MARY'S HOSPITAL; LECTURER ON
FORENSIC MEDICINE AT WESTMINSTER HOSPITAL.

THE duty of a coroner is to hold inquests on: (1) cases of death under certain circumstances; (2) treasure trove; (3) fires in the City of London. We are only concerned here with the medical aspects of the coroner's duties.

The object of an inquest is to ascertain if death is due to criminal, avoidable, or natural causes; further, to enable the guilty to be brought to justice, and to prevent and to limit accidents. Cases of death occurring in certain institutions are made by statute the subject of a coroner's inquest; this is done mainly to satisfy the public and the immediate relatives, so that any criticism directed towards those who were responsible for the custody of the deceased during life may be properly inquired into. Deaths from accidents in mines or factories fall into the same category, where the factory inspector must be informed by the coroner. Inquests of this type are just as much in the interest of the medical profession as in that of the public.

Information.

The circumstances in which an inquest is to be held in cases of death are stated thus in Section 3 (i) of the Coroners Act, 1887: "Where a coroner is informed that the dead body of a person is lying within his jurisdiction, and that there is reasonable cause to suspect that such person has died either a violent or an unnatural death or has died a sudden death of which the cause is unknown, or that such person has died in prison or in such place or under such circumstances as to require an inquest in pursuance of any Act," the coroner is to proceed to summon a jury and hold an inquest, whether the cause of death arose within his jurisdiction or not. It follows that a coroner does not take action until he receives information. Such information may come from any one of six sources: (1) his officer; (2) the police; (3) a registrar of births, deaths, and marriages; (4) friends or relatives of the deceased; (5) medical practitioners (in attendance during life or after death); (6) private individuals. The duty of informing a coroner of a death, where it may be deemed desirable to hold an inquest, is not thrown on any person or persons by statute, except in the following cases:—

1. A manager of an asylum in cases of insane persons under his charge.
2. Cases of judicial hanging by the sheriff (who must inform the coroner prior to the execution).
3. Deaths in prison.
4. Deaths which come within the scope of the Infant Life Protection Acts.

Registrars of births, deaths, and marriages are instructed by the Registrar-General to report to the coroner all deaths:—

1. Occasioned directly or indirectly by violence.
2. Occurring under suspicious circumstances.
3. The cause of which is stated to be unknown.
4. Which are stated to have been sudden, and respecting which no certificate issued by a medical man is produced.
5. Of infants in houses registered under the Infant Life Protection Acts.

The coroner, having decided to hold an inquest, must do so within reasonable time of the death,

although there is no statutory time limit laid down, and it is worthy of note that in one case the inquest was not held until 19 years after the death. Inquests have been threatened, or even held, upon bones, as to which it has been evident that they belonged to more or less remote antiquity. To hold inquests in such cases is obviously unnecessary. In exhumation cases a considerable time may elapse between death and the inquest. It is the duty of a coroner to hold an inquest on any portion of a body that may be found.

Medical Man as Informer.

When information has reached a coroner, he causes his officer to make inquiries, and as a result of the latter's investigations he decides whether or not an inquest is to be held. The duties of a medical man in relation to a coroner are all too vaguely laid down. By the Registration of Births and Deaths Act, 1874 (Section 20, Subsection 2), it is ordered that, "In case of the death of any person who has been attended during his last illness by a registered medical practitioner, that practitioner shall sign and give to some person required by this Act to give information concerning the death, a certificate stating to the best of his knowledge and belief the cause of death," the subsection giving particulars as to how the certificate is to be dealt with. There is a need, however, for specific statutory directions to the medical man as to what he is to do where he cannot conscientiously give a certificate as to the precise cause of death, whether he believes it to be a natural death or not. In practice he will generally inform the coroner if he finds that no one else is obliged to do so, particularly where he knows or has reason to think that death is not due to natural causes, or he will give a certificate so worded that the registrar will refuse to act upon it, and will inform the coroner. It may not be necessary for the medical man to inform the coroner himself, in fact, neither under this Act or any other Act is there any legal obligation for him to inform the coroner. In practice, however, he can gain nothing by following the letter of the law, for the coroner is bound to receive information from other sources eventually, and the net result of this strictly legal proceeding on the part of the medical man would be a general delay of the proceedings and a general inconvenience to all concerned. The medical man, on the other hand, is warned to be certain of his facts before he gives information to a coroner, for should his reasons for his action be unsubstantiated by fact, he may find himself in a very false position at a later period.

Accepting the principle that it is a duty of the medical man to inform the coroner in cases which are likely to be the subject of a coroner's inquest, the next point is what type of case should be notified. Many cases leave the medical man in no doubt as to his procedure, but there are a considerable number of cases in which one coroner would decide to hold an inquest whereas another would consider it unnecessary, for coroners interpret their duties very differently. Medical men are in a difficulty here, as by reporting some cases in which a coroner does not hold an inquest they may incur hostility from relatives, and, on the other hand, by reporting too few their action may be criticised by the coroner. To overcome this difficulty, the prudent medical man will soon learn the idiosyncrasies of the coroner of his district and act accordingly. He may, however, find a simple course in difficult cases and one which is quite in order—namely, to give a death certificate and at the same time inform the coroner that he has certified, and also of the salient facts of the case.

The following rules may assist him:—

1. Report if there is a history of an accident, no matter how remote.
2. Report to the coroner (if he does not consider that he can conscientiously give a certificate assigning a natural cause for death) any facts which cause him to abstain from doing so or which point to the case being one for an inquest under the section of the Coroners Act quoted above. He

will remember that the coroner is to act where he has "reasonable cause to suspect" and that a coroner has jurisdiction to hold an inquest, and is justified in doing so, "if he honestly believes information which has been given him to be true, which, if true, would make it his duty to hold such an inquest."¹

3. Take no action in cases of suspicion only, unless the details on which the suspicion is based are capable of being substantiated in the witness-box.

4. Report those cases where the medical man knows that if he does not report someone else will.

Officer's Inquiry.

As soon as the information is lodged the coroner's officer is directed to make inquiries. Such inquiries are almost certain to include the practitioner involved. The practitioner should be at all times willing to help this officer in every way, but at the same time he must remember that the statement he makes to the officer, although of no legal import, is used by the coroner as the basis of his examination of the practitioner in the witness-box. He must, therefore, be guarded in what he says. Further, as this examination by the coroner's officer is not a legal proceeding, the doctor may refuse to answer any question, especially those involving the confidential relations of doctor and patient, and those which may in any way reflect on his professional capabilities or conduct. But bearing this in mind, the practitioner is urged to be open in his dealing with this officer, as a refusal to give information, although quite within the rights of the practitioner, may place him in a false position at the subsequent inquest. Regarding the confidential relations of doctor and patient, the practitioner should decline to give any information to the coroner's officer. He should wait until questions involving this relationship are put to him in the witness-box and then only answer them after his professional protest has been over-ruled.

Post-Mortem Examination.

The coroner, having decided to hold an inquest, issues a warrant and summons various witnesses to attend. In the case of the medical man he may receive also an order to make a post-mortem examination, and, if necessary, an analysis of the viscera. The analysis being a specially skilled process should only be undertaken by a trained toxicologist, and no coroner would expect the medical practitioner to undertake it. The performance of a post-mortem examination is generally delegated to the medical practitioner associated with the case, but there is a growing tendency amongst some coroners to employ skilled pathologists for this purpose. The practitioner associated with the case should be present.

The holding of a post-mortem examination rests entirely with the coroner, who is naturally guided by the statements taken by his officer from the medical man and others. Here again there is a need for caution lest the coroner is led to think that the medical man is so satisfied as to the cause of death that no post-mortem examination would be necessary. It cannot too often be emphasised that if a case has features which make it a proper subject of a coroner's inquest, it is almost always advisable to hold a post-mortem examination. Over and over again the interests of justice have been defeated or jeopardised by the failure of a coroner to order an examination. However, in justice to the coroner, it is fair to say that often the complete failure of a local authority to provide suitable facilities for this purpose has influenced him in his omission. The Public Health Acts in the majority of cases only give power to the local authority to provide mortuary and post-mortem accommodation, but do not make it compulsory. In certain instances there is no doubt that avoidance of post-mortem examinations and of toxicological analyses is dictated on the grounds of economy.

Medical men should beware of making a post-mortem examination unless they receive written

authority from the coroner to do so. The body is under the absolute jurisdiction of the coroner, and even if he should give verbal consent such as "I do not order a post-mortem examination, but you may make one yourself if you like," on no account should the medical man act, for, should any future question arise, the doctor will be unable to shelter under the coroner, who has only power to act in the prescribed form. In such a case the doctor, of course, gets no fee for the examination. In important cases a skilled pathologist is sometimes called to make a second examination, which can only be legally done through a request made to the coroner by the jury. When a post-mortem examination is made, in every case without exception all organs, including the brain, must be examined by the medical man personally, and the work should not be delegated to the attendant. Those present at the examination, other than the attendant, should be persons authorised to be there by the coroner in writing.

During the examination, if the medical man as the result of his investigations has any suspicion that the deceased has died from the effects of poison, or is unable to exclude poison, it is his duty to place the whole (not portions) of the more important organs into perfectly clean stoppered jars which he himself has cleansed just prior to use, preferably each organ in a separate jar. He should on no account add any preservative. By this means the liver, kidneys, stomach and contents, bladder and contents, and intestines in ordinary cases, and other organs in special cases, should be reserved. The jars should be made of glass entirely, as, for instance, a jar involving the use of indiarubber bands is unsafe, for a portion may be detached and become intermingled with the viscera, with the result that the analyst would probably find antimony to be present, as manufactured indiarubber often contains this metal. Such has actually happened in one case. The jars should be tied down effectively and sealed with a seal. Each jar should be labelled with the name of the deceased, date of examination, nature of contents, and signed by the person performing the examination. These jars should be handed to the coroner's officer and a receipt obtained for them. The coroner should be then informed that in medical opinion an analysis should be made. Too much care cannot be exercised over these details, which are so often neglected. Points of this kind are sometimes challenged by the defence, should a criminal charge supervene.

In cases where it is possible that the professional conduct of a medical man may be questioned by anyone, the coroner wisely directs another medical man to make the post-mortem. In such cases the medical man concerned may elect to be present himself or be represented at the examination by a colleague, to which the coroner usually gives consent although he is not in any way bound to do so. Similarly, an accused person or one who may be possibly the subject of subsequent proceedings, may also be represented by a doctor at the examination. The medical man should make careful notes at the time of or directly after the examination of all his findings. Where a witness on oath before the coroner has ascribed death to negligence or improper treatment by a medical practitioner or other person, "such medical practitioner or other person shall not be allowed to perform or assist at the post-mortem examination."²

It will be remembered that in the recent trial of Dr. Hadwen a point was made for the defence that he had not been given an opportunity to be present at the post-mortem examination of the deceased child. If authority was cited for any right of a medical man, or any other person, charged to be present on such an occasion it was not reported in the newspapers.

¹ Rex v. Stephenson, 13 Q.B.D., 331.

² Coroners Act, 1887, Sec. 21, Subsec. 2.

Evidence at Inquest.

The coroner is not bound in any way to follow the rules of evidence which are strictly observed in other courts. He may take or refuse any evidence or testimony that he pleases. It is customary in all courts for the witnesses to remain outside the court until they are called to give evidence, after which they are allowed to remain in the court. The medical man, however, whose testimony is often taken last, is permitted to be present during the whole of the proceedings, as is the custom in other courts. His position is one of an expert witness and his presence in court is considered desirable so that he may hear the evidence given that it may assist him in arriving at his opinion as to the cause of death. Nevertheless, the coroner, as also the magistrate or presiding judge in other courts, may direct the doctor to remain outside the court until required.

Having been sworn, the medical man should give his evidence briefly and clearly, avoiding the use of technical terms wherever possible, and if such are necessary he should explain the same in simple phraseology. Above all, he should never be tempted to take up the position of lecturer and give the coroner and jury a discourse or a verbose account of what in his opinion were the circumstances of the death. Such advice appears to be superfluous, but evidence, if it may be called so, of this type is still too often given in these courts. The medical man must remember that the coroner's court is also a court of record, and that everything pertinent to the case is taken down in writing by the coroner or his clerk, and that he is subsequently called upon to sign this written statement. This document comes into the hands of the presiding authority of other courts, civil or criminal, and anything the doctor has said at the coroner's court in an unguarded moment may be thrown at him subsequently, with the result that he may be made to look foolish. When he has completed his evidence the coroner will read the transcript over to him and he will sign the statement. If he is in any way in doubt about what is written, he should make corrections at the time and read for himself carefully what is written, as once he has signed no correction may be made. He will then be bound over in a certain sum to attend at some other court in due course, if the case is to go further.

These remarks apply to every inquest, no matter how straightforward the case appears to be, and it must be remembered that there is always the possibility of any case being reopened in civil or criminal courts.

Fees.

Medical witnesses are by law (Coroners Act, 1887) allowed one guinea for attending to give evidence, or two guineas for making a post-mortem and giving evidence. No provision is made for mileage or for adjourned sittings, at all of which the medical man is bound to attend, unless specially released by the coroner. There has always been some doubt whether resident medical officers of institutions, whose duties are to attend on the inmates of institutions such as lunatic asylums, hospitals, infirmaries, &c., are entitled to receive fees. So far as hospitals supported by voluntary contributions are concerned, the medical man is not entitled. The test usually adopted is whether the institution is supported by voluntary subscription or not. It has always been customary for medical officers of those not supported by voluntary subscription to be paid, but recently in some cases payment has been refused. The wording of the Act is obscure, and a test action to settle the point would be an advantage. If it can be upheld that medical officers of infirmaries can be refused their fees, it seems likely that all institutions in which sick persons are attended may be interpreted as coming under the scope of Section 22 of the Coroners Act, 1887. The matter is under acute dispute just now.

Anæsthetic Deaths.

From the purely legal aspect it would seem clearly the duty of the coroner to hold inquests in this class of case. Exactly what is meant by the terms "anæsthetic death," or "death from anæsthesia," is very difficult of definition. The anæsthetic is usually deemed to be finished as soon as the patient is "round from the anæsthetic." In most cases as soon as this stage is reached the patient is deemed, so far as the coroner is concerned, not to have died from the effects of the anæsthetic. It is obvious that in many cases where operations are followed by death inquests are unnecessary. The anæsthetist is quite aware that the patient may not survive the operation owing to the gravity of the condition. On the other hand, where an apparently healthy person undergoing a minor operation, or even a major operation which is not an emergency, dies under the anæsthetic, it is eminently desirable for an inquest to be held. No medical man has anything to fear if his procedure was appropriate to the circumstances. The surgeon has been held at law to be responsible for everything which takes place in the operating theatre, and his testimony at the inquest is as important as that of those who in the eye of the law are his assistants.

Infanticide.

It is the duty of a coroner to hold an inquest on all newly-born children where there are any suspicious circumstances relative to the death, and in certain cases under the Infant Life Protection Acts. There is, however, in this case a difficulty. A still-born child is not a person within the meaning of the Coroners Acts, and in many cases live birth can only be proved by a post-mortem examination. A coroner, however, who has reason for thinking that a child may have been born alive, can decide to hold an inquest, and having so decided can order a post-mortem examination. If the examination establishes still-birth the right course appears to be that, evidence to that effect having been given, the inquest should conclude with a verdict of still-birth and that the coroner should then give his order for burial of the body in accordance with the Births and Deaths Registration Act, 1874, Section 18, c. Further legislation will no doubt deal with still-births in relation to inquests, for which the law at present makes no specific provision.

Reports and Analytical Records.

AGOTAN.

(HOWARDS AND SONS, LTD., ILFORD AND LONDON.)

WE have received a bottle of Agotan tablets showing that the convenient form in which this preparation is put up and the care with which it is distributed have been maintained. Agotan, which is of value by increasing the excretion of uric acid and urates in the urine, is identical with the preparation described in the British Pharmaceutical Codex as Quinophan (phenyl quinoline carboxylic acid), though a higher standard of purity is claimed for it. We have noted in these columns previously the chemical constitution of the preparation, and welcome such efforts to keep in this country the manufacture of synthetic drugs whose value has been proved in practice. On this last point we may say that we have received professional evidence of undoubted standing.

OSTELIN.

(GLAXO, OSNABURGH-STREET, LONDON, N.W. 1.)

This is an elegant little preparation consisting of an unsaponifiable fraction of cod-liver oil suspended in glycerine so that 3 minims are equivalent to 1 drachm of the original oil. The use of the preparation is obvious where the ordinary administration of cod-liver oil is attended with difficulty. The proprietors publish an interesting pamphlet from their medical department in which X ray photographs are given of the

various stages observed in a case of rickets treated with ostelin in a London hospital. The brochure indicates the value of the preparation as an anti-rachitic factor, suggesting that its use to prevent dental diseases in children follows on the lines of the experiments published in the *British Medical Journal*¹ last August by Mrs. May Mellanby.

"GADUS" JELLY.

(HEYERDAHL PRODUCTS CO. (ENGLAND), LTD., 36, REGENT-STREET, CAMBRIDGE.)

This preparation of cod-liver oil is also devised to make the administration of cod-liver oil pleasant to children. The jelly is manufactured from high quality Norwegian oil under the direct supervision of experts and is so flavoured that, although 30 per cent. of cod-liver oil is present, the fishy flavour, which is nauseous to some more than others, is concealed. The specimen jar sent to us contained approximately 80 teaspoonfuls, and the recommended dose varies from one level teaspoonful to two level tablespoonfuls per diem, according to the age of the subject. We need not expatiate on the use in many directions of a cod-liver oil which is agreeable to small patients, for the answer which children make to regular dosage in suitable cases is familiar to us all.

OXOID GLAND PREPARATIONS.

(OXO, LTD., THAMES HOUSE, LONDON, E.C. 4.)

The firm of Oxo, Ltd., now manufactures a large selection of organo-therapeutic gland products, comprising ampoules of liquor hypophysis and adrenalin solutions, suprarenal gland tablets, anterior and posterior lobe tablets, and also a varied assortment of pituitary and thyroid gland tablets—ampoules of liquor hypophysis 10 per cent. (0.5 c.cm.), and 20 per cent. (1.5 c.cm.) suprarenal gland tablets and adrenalin tablets. All these preparations have been tested physiologically and adjusted to a uniform standard of activity, and many or all of them have been noted at different times in medical literature. The way in which the preparations are put up for storing or for distribution is excellent in its convenience, while the range of dosage is large. The value of the gland products becomes yearly more widely recognised by the medical profession, making the need all the greater that the profession should be able to rely upon standard manufacture.

(1) ATOPHAN; (2) VERAMON.

(A. AND M. ZIMMERMANN, LTD., 3, LLOYD'S AVENUE, LONDON, E.C. 3.)

1. Atophan or Acidum Phenyleinchoninicum, which has also been noticed under the name of Phenoquin, has been found to facilitate the elimination of uric acid in gout and rheumatic affections, and in the columns of THE LANCET reference will also be found to the value of the preparation in neuralgia and sciatica. The preparation is put up in boxes of 20 tablets, each containing $7\frac{1}{2}$ gr. Even in a dose of this kind a definite increase in excretion of uric acid within an hour can be observed. The action is attributed to some alteration in the fermentative processes which regulate the oxidation of the purin bases, but precaution should be taken in raising the doses as unpleasant effects have been known to occur. Some interesting observations on the use of this drug will be found in THE LANCET, 1915, i., 1092, reporting the work of Dr. P. Biffis, whose results were published fully in *Il Policlinico*. The tablets are best taken after meals and swallowed whole followed by a glass of water.

2. Veramon. This preparation has now been in the hands of the medical profession for some three years, and clinical evidence is forthcoming of its merits as an analgesic especially in peridontitis, neuralgic headache, and migraine. It has also been found to relieve the headache accompanying intestinal disorders. The compound is a combination of amidopyrin and veronal.

¹ August 30th, 1924, p. 354.

PETROLAGAR.

(DESHELL LABORATORIES, LTD., SENTINEL HOUSE, SOUTHAMPTON-ROW, LONDON, W.C. 1.)

We have received samples of this emulsion of medicinal liquid paraffin and agar-agar. Petrolagar is sent out in two forms, with and without phenolphthalein. The emulsification of the mineral oil tends to increase efficiency as an intestinal lubricant, while the agar-agar mechanically aids the action of the bowel from its well-known physical qualities. The addition of phenolphthalein gives a purgative action to the mixture, of which advantage can be taken in suitable cases. Practitioners will find this preparation very suitable for patients where bowel action is obstinate and capricious, where it is desired to avoid the use of aperients, or where such medicines have failed to regulate the mechanism.

Asparol (Chem. Fabrik. J. E. Stroschein, Berlin) is stated to be calcium caffeine acetylsalicylate. Its use is indicated in cases where the administration of salicylic acid or acetylsalicylic acid and caffeine is likely to be beneficial. Its analgesic action is said to be prompt and lasting, and it is claimed that the presence of the calcium inhibits the action of the caffeine on the heart. It is also stated on medical authority that the drug is far better tolerated than acetylsalicylic acid and caffeine.

New Inventions.

THE HERMIT FOOT SUPPORT.

I HAVE tested recently a foot support for use in bed, and several of my patients speak very highly of it. Everyone knows how uneasy it is to take meals in bed, or to read or write, on account of the constant

tendency to slide down the bed. In the "Hermit" support the difficulty is solved, as the apparatus is adjustable to the length of the individual, whose feet can be kept in constant contact with it. As will be seen from the illustration, it consists of a framework capable of being extended in length and padded at one end as a support for the feet. By its use the whole tension is taken away from the bottom of the back, thereby relaxing the muscles there, and consequently giving a more comfortable position when sitting up in bed; it is of particular use where anyone has to be propped up in bed for heart trouble, chest complaints, and after operations. Mr. Herbert Mitchell, of Bradford, is the inventor.

Bradford.

WILLIAM F. RAWSON, F.R.C.S. Edin.

THE LANCET.

LONDON: SATURDAY, JANUARY 3, 1925.

ALASTRIM OR "PARA-SMALL-POX" ?

THE fact that the Registrar-General's returns for the year just passed have chronicled about 3000 notified cases of small-pox occurring at different times in nearly 100 English sanitary districts without entailing any appreciable mortality, taken with the evidence from many sources of the very slight character of the notified illness, lends a special interest to the review entitled *Alastrim and Variola* which appeared in the October number of the *Bulletin* of the Office International d'Hygiène Publique, and of which a translation was given in the last two issues of THE LANCET for 1924. This scholarly and practical study we owe to the distinguished epidemiologist and professor of hygiene at Lisbon, Dr. RICARDO JORGE. He has reviewed the epidemiology of the special type or variety of small-pox characterised by persistent benignity in different countries during recent years, describing its presence and characteristics in parts of Africa, Central America and the West Indies, in Brazil, in Australasia, and in Europe, as well as in a recent and instructive outbreak in the Azores. These epidemics are described under different names, such as *alastrim*, *amaas*, *para-variola*, and "mild small-pox." In all of them, Dr. JORGE points out, there are common characteristics so striking as to justify the conclusion that, however closely the epidemic disease is connected with or related to small-pox, it has qualities which, both for practical and scientific purposes, require to be differentiated from the *variola* or small-pox which is ordinarily understood and described in the text-books. In this contention Dr. JORGE is by no means oblivious of the fact that, from the time of SYDENHAM and from pre-vaccination days, classical small-pox has shown variations from epidemic to epidemic in its general severity, and that, occurring as it does in these days among populations which to a large extent are protected by vaccination, each epidemic comprises a series of cases of mild or abortive small-pox in which the modification has resulted from incomplete vaccinal protection. But, in regard to *alastrim*, *amaas*, or "mild small-pox," it would appear that the characteristic benignity is not a factor of immunity acquired by the individual as a result of previous small-pox or of vaccination, but is inherent in the type of the infection itself. The well vaccinated escape *alastrim* just as they escape small-pox; there is no dispute about the efficacy of the protection conferred. But, on the other hand, the unvaccinated, when attacked by *alastrim*, get through the disease, as a rule, with little more disturbance constitutionally than happens with chicken-pox or other infectious maladies which are usually considered of minor importance. Even when the rash is abundant and confluent in the early stages the patient hardly feels ill, and his eruption habitually dries up with little pustulation and rarely leaves scarring or pitting. No one who was familiar

with small-pox as it occurred, for example, in London in 1893 and 1902, or as it occurred as recently as 1921 in Glasgow, can fail to realise the contrast between such a disease when unvaccinated children are concerned or older adults who have not been vaccinated since infancy.

Dr. JORGE has included a discussion of recent English "small-pox" in his survey, making use of the clinical accounts by GARROW, PAINTON, JAMESON, and others, as well as of the information supplied to the Office International d'Hygiène Publique by the British delegate, Sir GEORGE BUCHANAN. He finds in these accounts evidence which convinces him that the disease which we are now notifying and reporting as small-pox belongs to the class of *alastrim* epidemics in other parts of the world. Special attention is drawn to the parallel occurrences in Switzerland, where during the last three years the total reported cases have been 3900, the number of deaths only three, and the individual cases throughout have hardly ever merited the term severe. These observations, which accord with much that has been written and suggested in this country on the subject, notably by Dr. S. M. COPEMAN, are of practical as well as academic interest. The contrast which Dr. JORGE draws between the position in this matter of "unicists" and "dualists" is instructive and particularly worthy of study. As he points out, the uncompromising "unicist" is in a position of some difficulty in relation to the advocacy of vaccination on which he is accustomed to rely—namely, as an effective and necessary preventive of the severe or classic form of small-pox by which we may at any time be invaded. If vaccination is advocated as a protection against the severe type while we insist at the same time that the benign type should be diagnosed and notified as small-pox without any differentiation, the public receiving the propaganda is apt to become bewildered or mistrustful. On the one hand, it is asked to accept rigid systems of vaccination and hospital isolation, sometimes under legal compulsion, in order to ward off a terrible disease; on the other hand, the terrible disease, when it appears and comes to its doors, is no more alarming than chicken-pox, and has so far shown no signs of possessing a potential or inherent danger of being transmuted into the redoubtable form. The other side to the picture is that the prudent "dualist" admits that if he has to see an individual case, in its early stages, with no knowledge whatever of the epidemic of which it forms part, he cannot with any certainty diagnose it as *alastrim* and not small-pox, or vice versa. He is in the same position as with a case of enteric fever where he has no bacteriological aid to determine between typhoid and paratyphoid infection. Dr. JORGE reviews several points of possible differentiation, such as the character of the rash and immunity and allergic reactions, emphasising the need for further investigation and research in these directions, but without finding any absolute criterion as between *variola* and *alastrim* decisive for the individual case.

Looking to the question as a whole we believe that there will be a large measure of agreement with his main contention—namely, that for clarity of thought as well as for administrative convenience it has now become necessary to adopt a special term to designate the characteristically benign type of small-pox (in the generic sense) which is now extensively prevalent in different parts of the world. The term "mild small-pox" is not of itself sufficient, inasmuch as mild cases occur with every epidemic

of classical small-pox, and severe cases may occur, though rarely, in course of the benign epidemics. "Alastrim" has much to commend it historically and etymologically; it signifies merely a disease which is scattered, and it can be used without prejudice to any controversy. The alternative "para-small-pox" (or "para-variola") has advantages from the point of view of analogy, from its including a reference to the disease with which it is so closely akin, and because no new position would be created in the matter of notification. On these grounds, perhaps, it may be preferable to ignore the unpleasantly hybrid nature of the word "para-small-pox" and adopt it boldly for our working purposes. The decision here seems to rest with the Ministry of Health and those who determine official nomenclature in regard to infectious diseases.

THE STIGMA OF NEUROSIS.

THE evolution of official terminology from "mad-house" through "lunatic asylum" to "mental hospital" shows that there is a great deal in names when they involve prejudice, and any change in nomenclature is justified that helps to remove the notion that the mental sufferer is a guilty encumbrance to be hidden away so that he cannot offend. But the expression of prejudice in names is still current in the sphere of those minor psychoses that rarely involve certification. "Shell-shock" was a respectable disability, whilst the alternative and correct diagnosis of hysteria was, and often still is, suppressed on account of the attached opprobrium. A patient may have a gastric or vaso-motor "neurosis," but he must not be "neurotic" on pain of social or family ostracism and, we fear, some degree of professional neglect. There is, indeed, a distinction between "neurotic" and "neurasthenic" which involves a subtle moral judgment. If we accept inquest reports as a basis of observation we find that the sufferer from neurasthenia often commits suicide whilst the neurotic never does; thus the latter may demonstrate, by suicide, his right to the more respectable diagnosis. The phrase "nervous breakdown," however, involves nothing blameworthy, and a recent lay writer describes under that title the mental trouble from which the elder PITT suffered, though the description makes clear that the condition was one of anxiety hysteria.

This medley of prejudice and pseudo-diagnosis is partly responsible for that astonishing amount of suffering and disability in the domain of the psycho-neuroses to which Dr. EDWIN GOODALL referred in a recent issue of THE LANCET (Dec. 20th, 1924, p. 1275), and for which our Scottish correspondent in the present issue gives chapter and verse. The obloquy carried by such words as "hysterical" or "neurotic" is accompanied by a belief that the patient is to blame, that he need only use common sense and will-power to rid himself of his difficulties, and that neurotic suffering is best treated by "wise neglect." This belief will often be supported by the practitioner who has not followed the progress of psychopathology. It is regarded as a sad injustice when a patient with an organic disability is wrongly thought to be hysterical or neurotic, but, though an error in diagnosis is always regrettable, it is our peculiar attitude towards the neurotic that makes this particular mistake so distressing. Yet the denial of help to the mental sufferer is a greater injustice, and the patient who needs treatment for his mental state is often not even given the opportunity to

describe the symptoms for which he would welcome relief.

This same medley is allowed to form the equipment with which many a practitioner, even after holding hospital appointments, sets out to handle the problem of the psycho-neuroses in general practice. Systematic instruction in psychopathology hardly exists, though its foundations are now well established, and that it receives little attention in the general curriculum is suggested by the fact that the candidate for a qualifying examination would never expect to be questioned, say, upon that common clinical phenomenon connoted by the phrase "a nervous breakdown." In fact, his hospital training teaches him that all clinical interest ceases when once a diagnosis of neurosis is established. Certainly the neurotic patient seems to have a legitimate grievance, but it is one that bids fair to be removed or alleviated. More instruction is being given to-day in our medical schools along the indicated lines, as the teachers themselves are becoming more impressed with its necessity. And here we have a direction in which medical training can be improved practically without additions to a crowded curriculum.

QUININE IN MALARIA.

ALTHOUGH the discovery of the cause of a disease is rightly regarded as a necessary preliminary to the establishment of rational as opposed to empirical treatment, it often happens that many years of patient study are needed before the full practical results of the discovery come to fruition. Thus the causal organism of pulmonary tuberculosis was identified in 1882, and after the lapse of 40 years we remain baffled in our attempts to formulate a direct method of attack, based on our knowledge of the cause of the disease. Again, the virtue of cinchona bark as an empirical remedy for malaria was known and utilised more than 200 years before the malarial parasite was first seen and described by LAVERAN in 1880. Since that date a vast amount of research work has been done, much of it recent and inspired by the experiences of the war; yet we remain in ignorance as to the precise manner in which the good effects of quinine are brought about, nor is there any approach to unanimity as to the dosage, method of administration, or even the preparation of quinine or other cinchonoid alkaloid from which the best results may be expected. The careful and closely reasoned criticism of the methods of treatment of the malarials by Lieut.-Colonel CLAYTON LANE, which appears in the *Tropical Diseases Bulletin*,¹ is on this account particularly opportune, and merits the close attention of all who are interested in malaria. Among many points of importance a few may be selected as of special interest. There is experimental evidence to show that, within a few minutes of the injection of a solution of quinine into the blood-vessels of a rabbit, 90 per cent. of the amount injected has disappeared from the blood. Of this a moiety, variously estimated as 15-65 per cent., is excreted in the urine; the remainder is stored in the organs of the body, more particularly the kidneys, spleen, and adrenals, where in course of time it is broken down or "metabolised" into substances of unknown nature. The rapid disappearance of quinine from the blood makes it difficult to believe that its virtue lies in any direct poisonous effect on the plasmodia, and it must be presumed that its action depends on the production,

¹ 1924, vol. xxi., No. 11.

directly or indirectly, of bodies of unknown nature, which combine with the malarial organism and destroy it.

Of the numerous observations undertaken with the object of determining the line of treatment most likely to be successful in eradicating the parasites from victims of relapsing malaria, Colonel LANE singles out for special notice two sets of experiments, the Macedonian cases recorded by A. G. ANDERSON, and the Liverpool series by J. W. W. STEPHENS. In each series the conclusion has independently been reached that the efficacy of quinine in the prevention of relapse varies according to the time of year, the period of greatest efficiency coinciding with the warmer months. In assessing the relative value of different methods it is clearly of the greatest importance to recognise and make allowance for this underlying seasonal influence, and the failure to do so must be regarded as vitiating the results arrived at in much of the experimental work on the subject. No proof appears to be forthcoming of the widely held view that quinine is effective mainly or exclusively against extracorporeal organisms. On the contrary, there is evidence that plasmodia are vulnerable to the influence of quinine in all but the terminal phase of intracorporeal growth. It is concluded that the practice of timing the administration of quinine so as to correspond with a special phase of the life-cycle of the organism is not supported by scientific evidence. In discussing the much debated subject of intramuscular quinine stress is rightly laid on the experimental work bearing on the unfortunate sequelæ that may follow the injudicious use of the intramuscular route. On the other hand, while oral administration suffices for all ordinary purposes, it must be recognised that there are cases in which, for one reason or another, quinine requirements cannot be fully met by the oral method, and in these cases we believe that the value of the alternative route, as a temporary means of supplementing or replacing oral quinine, has been amply demonstrated. The clinical experience of the war, in which the aggregate number of intramuscular injections was very large, shows that, provided due care is taken to prevent sepsis and to avoid injury to nerve trunks, the risk of serious local complications involving permanent disability is very small indeed. Perhaps the only circumstance in which the intramuscular method should be absolutely prohibited is the concurrence of a debilitating condition, such as chronic dysentery, with malaria; in such cases intramuscular injections of quinine are likely to cause widespread necrosis of muscle and abscess formation, and therefore should not be prescribed. The review concludes with a short account of recent work on the comparative values of quinine and other alkaloids derived from cinchona, such as cinchonine, cinchonidine, and quinidine, in the course of which a considerable discrepancy of evidence is disclosed, and it is clear that the subject is one on which further research may profitably be undertaken.

The problem of the treatment of malaria presents peculiar intricacies. When it is remembered that there are three forms of malaria, differing not only in biological and clinical characters, but also in their therapeutic reactions; that there are a number of cinchonal alkaloids, mostly of proved value, but of which the relative efficacy awaits exact determination; and further, that there exists a seasonal factor which directly influences the results obtained by treatment, the difficulties of a scientific investigation in which so many variables have to be taken into account are readily realised.

AN OLD HIGHLAND FARM.¹

To have compiled a book which is not only interesting but eminently readable out of an ill-kept, incomplete, and what would now be called illiterate account book is a literary feat of which Miss Grant may well be proud. She has produced a lifelike picture of Highland rural life at a date when what was practically mediæval feudalism as it existed in England, say, in the fourteenth century, was still in being. William Mackintosh, of Balnespick, whose account book between 1768 and 1782 is the foundation of Miss Grant's work, was born sometime before the year 1745, being infeft—i.e., enfeoffed—into Balnespick in 1743, which estate he sold to Macpherson of Invereshie in 1748. At the date of his account book he held a tack—i.e., lease—for "Three nineteen years" from the Chief of Mackintosh of the Davoch of Dunachton and Kincraig in the parish of Alvie on the upper reaches of the Spey. The position of the tacksman was as follows. Of the land which he held from his chief he kept a portion in his own hands; the rest he leased to subtenants who farmed it on a sort of coöperative system on the same principle as village communities in mediæval England (v. Chap. VII.). As Dr. Scott points out in his preface, "it appears that the rents due from his subtenants nominally covered the chief rent he paid. That left him the produce of the portion of land he reserved for himself for his own maintenance." But "he was not dependent on the produce of the lands of Dunachton for his own living, since he had other sources of income." In a case where the tacksman had not the latter resources, continues Dr. Scott, there might have been some danger that the subtenants would have suffered. Anyway, they did not suffer under Balnespick's rule, for we find him acting as a beneficent landlord. He received and administered the pay of a man who was with the army, and despite the fact that the man was in debt to Balnespick the whole of the money transmitted in this way was spent on the man's family and the debt was not claimed until after his return. Balnespick also arranged marriage settlements, administered the affairs of widows and orphans, acted as a sort of bank, provided credit for the tenants, and formed an arbitrator in grazing disputes and the like. In fact, he carried out the feudal system at its best, a system which only fell because those who worked it would not remember that although those below them had duties to carry out, yet they themselves also had responsibilities to their inferiors. He was responsible for the distribution of such poor relief as there was, for the collecting of the minister's stipend and the schoolmaster's salary. What strikes a modern reader is the hardness of the farming life and how both the people and their animals were generally very near to starvation. The plough was as primitive as that described in the Georgics, and yet so small and weak were the cattle that it took a 12 ox team to draw it. Yet with all this they were a hardy and happy race, and no one who has studied the history of the British Empire will fail to remember what a debt that Empire owes to such men and their descendants.

THE University of Sydney is about to appoint its first professor of obstetrics, a new chair having been founded with the aid of a grant made by the New South Wales Government. This appointment will increase to eight the number of professors in the medical faculty, which includes one-third of all the students at the University. Applications for the chair are now being invited in this country as well as in Australasia, and should reach the Agent-General for New South Wales at Australia House not later than Saturday, Jan. 24th. A committee sitting in London will investigate the claims of candidates for this chair.

¹ Every Day Life on an Old Highland Farm. By L. F. Grant. With a Preface by W. R. Scott, M.A., Phil.D., Adam Smith Professor of Political Economy in Glasgow University. London: Longmans, Green and Co. 1924. Pp. 276. 12s. 6d.

Annotations.

"Ne quid nimis."

ACCIDENT BEDS IN LONDON.

THE appeal of the Metropolitan Hospital at Christmas for a large building fund was based partly on the fact that accidents have become so frequent in the neighbourhood as to render necessary a new casualty ward. In his speech at the meeting of the General Council of King Edward's Hospital Fund for London, which we reported last week, the Prince of Wales pointed out that one of the most important subjects dealt with recently by the Fund is the increased provision of accident beds. The hospital accommodation of the capital will presently be increased by 301 beds, of which 53 are to be reserved for accidents, several of the new grants in aid of schemes of capital expenditure being made conditionally upon a specified number of beds being set aside for emergencies. This welcome and long overdue expansion is the outcome of a recommendation made in March last by the Ambulance Cases Disposal Committee of the Fund, and to it must be added the 16 further accident beds which have already been made available at King's College Hospital. In themselves these are substantial additions to the means of dealing with cases of accident and sudden illness, but they are still far from being adequate to the constantly growing need. Guy's has 57 beds definitely attributed to casualties and accidents; St. George's, 38; St. Thomas's, 23; but in most cases the numbers are inconsiderable, while the smaller general hospitals and cottage hospitals have, at the best, only one or two, and in most cases none at all.

If street accidents only had to be provided for this provision would still be inadequate, especially in view of the disquieting fact that these accidents are steadily increasing. Whereas in 1907 17,065 cases of personal injury were reported by the police, 283 of which were fatal, in 1922 25,547 persons were injured and 675 killed. To these high figures must, however, be added cases of sudden illness, necessitating removal to hospitals or infirmaries; in 1922 there were just under 8000 such cases. There has been no comparable addition to casualty beds—indeed, during the last three or four years the provision had remained practically stationary until the King's Fund fortunately found itself in a position to take action. Notwithstanding the "Safety First" propaganda, which has done much to remind both pedestrians and drivers of vehicles that they are always responsible for their own lives, and often for those of others, accidents in the streets of London are unlikely to diminish. Carelessness, ignorance of the presence of danger, absence of mind, sudden loss of nerve, are contributory causes which will continue to exist so long as the human mechanism falls short of perfect action. Roadways and footpaths become more crowded every year, and thoroughfares that were comparatively peaceful a decade ago are now ceaselessly thronged. It is thus of real importance not only that there should be a sufficiency of casualty accommodation in the hospitals, but that it should be so distributed that it may not be necessary to convey seriously injured victims or persons seized with grave illness long distances through the overcrowded streets.

Rapidly as the voluntary hospitals have, generally speaking, recovered from the pecuniary shocks of the war and of the years immediately following it, they still have before them tasks, notably of extension and rebuilding, which will place a heavy tax upon their resources and upon the generosity of those who provide them. The fruition of those tasks will enable many of them to provide more adequately for emergency cases, but, more often than not, fruition will be delayed for years, and the need is immediate and increasing. An important contribution to the solution of the

difficulty would be afforded by such a relaxation of law and regulation as would enable wider use to be made of the vacant beds which are so often to be found in Poor-law institutions. Questions, for instance, involving anything in the nature of what used to be called "Settlement," should be ruled out— injured persons should be entitled to be admitted to such institutions without formalities or inquiry into their place of abode and allowed to remain there until they can be removed without prejudice to their condition. Most important of all is that they should no longer be technically "pauperised" by remaining for a short time under the care of the guardians. The "pauper taint" in such cases is a relic of barbarism, and to sweep it away would enable the Poor-law infirmaries to give powerful help to the overburdened voluntary hospitals, not merely in this, but in many other directions, as well as giving the more backward of them an incentive to improve their scientific and nursing equipment.

MYOPIA, A DISORDER OF GROWTH.

THE cause of that over-distension of the sclerotic coat of the eye in its posterior half which results in myopia is a perennial subject for discussion among ophthalmologists. It is generally taught that the main factor in its causation is an intermittent increase of intra-ocular tension during the period of growth, due either to the pressure of the extra-ocular muscles on the eyeball during convergence, especially in the stooping position, or to vascular engorgement due to the too constant use of the eyes for near work. Dr. F. W. Edridge-Green holds, and has recently enforced his argument in our correspondence columns, that the main factor in the causation is the increase of blood pressure which is attendant on the performance of any undue muscular effort. A lecture recently delivered to the British Optical Association by Sir Arthur Keith takes us back to fundamental consideration of anatomy and physiology in a way which those who are accustomed to confine their thinking to the bony limits of the orbit cannot but find both refreshing and helpful.

Starting from the premise, which will be generally admitted, that it is exceedingly rare for an eyeball which has remained normal until the twentieth year then to commence to elongate, Sir Arthur Keith lays it down that myopia should be ranked amongst the disorders of growth. Now the eye shares with the brain the peculiarity that there is in both, during the early years of life, a precocious growth. "By the end of the fourth year the brain has grown to 84 per cent. of its full size, the eye to about 78 per cent., while at this age a child's body attains only 21 per cent. of its adult size." After the fourth year growth, both of eye and brain, proceeds slowly and steadily, the adult dimensions being reached about the twentieth year. The brain is enclosed within a strong fibrous capsule in which are developed the cranial bones. How does the growing brain succeed in making its bony capsule grow in the required shape? Just how the activity of the osteoblasts is regulated is a problem that Sir Arthur Keith says he has not yet fathomed, but he is sure that in the gradual expansion of the outer coat of the eyeball we have an exactly similar problem. To realise the complexities of the problem he proposes to take the model of an artificial baby-eye, making the outside coat of a tough material woven out of an inelastic fibre like the outer cover of a pneumatic tyre. If we copy Nature, he says, we shall build the outer coat in such a way that it will withstand pressures and tensions ten times above that to which an eye is normally exposed. To do this it will be necessary to arrange the fibre-strands meridionally, equatorially, and diagonally in all directions, and also so that they pass from each layer to the next to bind them securely together. Having thus set up a baby-eye, and distended it with pressure equal to that which supports a column of mercury 25 mm. high, how are we to

bring about in it a gradual and regulated enlargement or growth?

This is the problem that has to be solved in the living eye, whose outer coat is formed in just such a fashion as has been indicated. We know that in every microscopic mesh of the fibre system there is a resident living unit. It is these fibroblasts that can bring about the required processes of growth and absorption and control the whole process by which the eyeball is shaped so as to withstand the internal pressure to which the eyeball is subjected. How the fibroblasts do their work we do not know. We may suppose that during the period of growth they are sensitive to the strains and stress imparted to their fibres by the intra-ocular pressure. But after youth has passed something happens and they are no longer sensitive; the process of growth ceases. To illustrate the sort of factors that influence the activity of the fibroblasts Sir Arthur Keith refers to the subject of acromegaly, a disease in which the mechanism which formally regulates the activity of cells or units which build fibrous tissue and bone is entirely thrown out of gear by some defect in the secretion of the pituitary body. Some comparable fault in the mechanism which normally regulates the growth of the sclerotic coat of the eye must be at the root of myopia. Neither excessive convergence, nor vascular engorgement, nor unusual muscular effort are in themselves adequate causes to originate myopia, though when once started all these may be adverse factors favouring its increase, a fact which justifies the advice usually given to myopes by the ophthalmic surgeon. Nor is it any real help to regard myopia as an adaptive action of Nature in an effort to bring the eyes of the moderns more into harmony with the requirements of civilisation. On the contrary, myopia is a defect due to a faulty action on the part of the fibroblasts which form the outer coating of the eye. What exactly causes that defective action is a problem as yet unsolved. Sir Arthur Keith has pointed out the direction in which we must look in order to solve it.

SANOCRY SIN IN TUBERCULOSIS.

Prof. H. Mollgaard, of the physiological department of the Veterinary College in Copenhagen, has recently introduced a new compound for the treatment of pulmonary tuberculosis. The substance is a double thiosulphate of gold and sodium, and has been named sanocrysin. It is used clinically in conjunction with a serum, the most valuable source of which has proved to be horses which have received injections of Dreyer's diaplyte tubercle bacilli. The steps which led to the combination of gold salt and serum were briefly these. Sodium gold thiosulphate was found to be a substance well tolerated by healthy animals such as rabbits or calves, in doses up to about 60 mg. per kilo. body-weight; the first serious symptom it produced was albuminuria, and the occurrence of this was avoided if injections were made of doses slowly increasing in size. A different picture was presented if doses of about 30 mg. per kilo. were injected into tuberculous animals; signs of severe shock appeared, notably fall of body temperature, serious albuminuria, and collapse; the animals suffered in a condition closely resembling that seen after the injection of tuberculin. Prof. Mollgaard arrived at the conclusion that in sodium gold thiosulphate he had an agent which produced in the body (as well as out of it) powerful lysis of tubercle bacilli, and that in order to make it of clinical value he had only to find a serum which was able to neutralise the effect of the toxins liberated when the bacilli themselves were lysed. He found serum prepared by the use of diaplyte bacilli the best for this purpose, and he succeeded in demonstrating a striking action of such serum in reducing the shock produced by the injection of the gold salt; the effect on the albuminuria was convincing. The practical outcome of Prof. Mollgaard's research has been to enable him to cure calves suffering from advanced pulmonary tuberculosis produced by the

injection of cultures of high virulence; the number of experiments made is sufficiently large to establish the therapeutic value of sanocrysin under these conditions. An extensive clinical trial has already been made in Denmark on about 450 cases. Dr. Secher has examined over 160 cases and has had a large number of striking successes in severe phthisis; it is at present not known which is the most favourable type of patient, but there is some indication that the acute though massively infected subject offers more hope than the long-standing chronic one. Dr. Secher is of opinion that the treatment will be of great value in ensuring the future health of cases of tuberculous pleurisy. Investigation in Denmark has shown that a very high percentage of such cases die within three or four years after leaving hospital. The further development of sanocrysin will be awaited with much interest. The *Northern News Service* reports the equipment of a factory in Copenhagen capable of dealing with 100 kilos. of metallic gold monthly.

SPECIMENS ILLUSTRATING SURGICAL METHODS OF EXPOSURE.

THE nucleus of a collection of anatomical specimens illustrating surgical methods of exposure has been prepared with considerable care by Mr. A. K. Henry and Dr. D. K. Milne Henry, and was shown by them on Dec. 12th last at a meeting of the Surgical Section of the Royal Academy of Medicine in Ireland. In the specimens demonstrated the various structures were appropriately coloured and labelled, and each specimen was accompanied by a legend which explained lines of incision, landmarks, and planes of cleavage by means of simple diagrams. This collection, through the courtesy of Prof. E. J. Evatt, was begun at the Royal College of Surgeons, Dublin, with the double purpose of helping students of operative surgery, and of creating what it is hoped may become something analogous to a library of reference for the practising surgeon. It was felt that the earlier the student is made to look to the disposition of parts as a thing upon which his own personal intervention might be acquired the better. Students learn and remember their anatomy with the skin off, and are often at a loss when a portion of a familiar dissection is screened off from the rest like a field of operation. It is easy to hang the anatomy of a whole region down to the minutest detail upon a surgical peg, and to demonstrate it by means of a surgical exposure. Again, actual preparations which can be studied at leisure may well give the surgeon information regarding the detail and depth of an exposure in a way that no picture could imitate. It is obvious that no amount of anatomical knowledge can replace the study of live pathology upon the operating table, but a clear appreciation of normal anatomy in the presence of pathological change is essential to good surgical work. Among the preparations shown at the meeting were: Exposure of the popliteal face of the femur from the outer and inner side, the Sprengel Smith-Peterson exposure of the hip-joint, and Royle's exposure of the lumbar sympathetic for rami-section in spastic paraplegia.

PUNCTATE BASOPHILIA.

AMONGST the many deleterious effects produced upon the body by chronic lead absorption, it has long been recognised that a moderate degree of secondary anaemia is a very constant one. The drop in the red-cell count is not generally great, the count being, as a rule, between 3-4,000,000 per c.mm.; but, as is usual in secondary anaemias, there is a more severe effect produced upon the haemoglobin content of the red cell and consequently the colour-index is low. Stained films show the presence of changes in size, shape, and tinctorial characters of the red cells; perhaps the most discussed and interesting of which is the presence of basophilic stippling which usually goes by the name of punctate basophilia. This condition, one of peppering with blue granules of

the erythrocytes whose ground colour is red when stained by the Romanowsky methods, is one of long recognition, having been described by Ehrlich in 1883, and it has been the subject of much research and debate both as to its origin and to its significance. It was early recognised not to be specific for any form of blood lesion, but to be found in a number of other conditions; it is present in the blood in embryonic as well as in early extra-uterine life, and it was noted by a number of observers as a frequent accompaniment of trench fever in the late war. Especial attention has been directed towards its presence in saturnism, in which it is frequently a well-marked feature of the anæmia. It may also be produced experimentally by lead, as well as by other toxic agents.

The nature of the condition has been widely discussed, its association with conditions of blood destruction and regeneration being generally admitted. One school held that it represented persisting fragments of nuclear chromatin, the residue of fragmented erythroblast nuclei, this being in conformity with the now generally rejected theory of fragmentation and disappearance of the normoblast nucleus. The second, and more modern school, considers it representative of a foetal stage in the development of the red cell in which the cytoplasm is largely basophilic, prior to the development of hæmoglobin. From this point of view the blue-stained granules would be persisting particles of a cellular structure, normal in the early development of the red cell, but absorbed and removed in its maturity. Their persistence indicates the production of imperfectly finished red cells by the bone marrow, a condition which in another slightly differing form is probably exemplified by polychromatophilia—a diffuse and abnormal bluing of Romanowsky-stained red cells. Such an output of imperfect cells might result from a marrow which is stimulated to increased production by the presence of an anæmia, and, at the same time, functions under the disabling effect of the presence of the anæmia-producing agent in the circulating blood and amongst its erythroblastic cells.

In a recent review of the specific effects of lead upon the blood cells, published in *Medical Science*,¹ the question of the mechanism by which lead produces these changes in the blood has been summarised from a series of papers published by Aub, Reznikoff, and Smith in the *Journal of Experimental Medicine*, this view of the nature of punctate basophilia, which is associated with the names of both Pappenheimer and Sabrazès, is accepted. An attempt is further made to analyse the direct effect of lead upon the red cells in the production of anæmia and, as the result of a long series of in vitro experiments, the somewhat mechanistic suggestion is put forward that insoluble lead phosphate is precipitated in the envelope of certain of the cells, which thereby renders these harder and brittler than the normal ones, with the result that they are rapidly battered to bits in the circulatory torrent; a theory whose simplicity appears to be its main attraction.

THE SUDAN SCHOOL OF MEDICINE.

THE twenty-second annual report of the Gordon Memorial College, Khartoum, contains an account of the opening of the Kitchener Memorial School of Medicine. It was one of the late Lord Kitchener's cherished projects that in addition to the College, in memory of Charles George Gordon, which he was so largely instrumental in establishing, the Sudan should also have its own school of medicine. On Feb. 29th, 1924, the new buildings of the medical school were officially opened by Major-General Sir Lee Stack, whose tragic death adds a third to the memories of great men associated with the Sudan. The cost of the new school was met partly by the generosity of private subscribers and partly by a munificent gift from the funds of the British Red Cross in Egypt, while an endowment fund is already well on its way

towards reaching the amount necessary to provide for the upkeep of the new medical school. The late Governor-General of the Sudan, who was also President of the Gordon College, made a significant statement in the course of his address at the opening ceremony when he said, "I am convinced that medical work is of the highest importance to administration." Such was also Kitchener's belief, and it is gratifying that six students from the Gordon College are amongst those who have commenced their studies at the new school under the direction of Dr. Oliver Atkey, Director of the Sudan Medical Department. The Gordon College continues to do useful work in the educational field, and from the medical point of view particular interest attaches to the work of the Wellcome Tropical Research Laboratories. Major R. G. Archibald, the director of these laboratories, contributes a brief report on the work which has been carried out. He himself was responsible for an important survey of the bilharzial problem, as a result of which bilharzia is now a notifiable disease, and measures for checking the spread of the malady have been established. The chemical section has carried out work on the chemical problems of cotton-growing, and the entomological section has continued its study of the various agricultural pests of the country. The Gordon Memorial College has lost much in Sir Lee Stack, for his sterling administrative qualities were of the greatest value in its varied activities, and he was particularly interested in the medical school.

TUBERCULOSIS OF THE KIDNEY.

A TUBERCULOUS infection which settles in the kidney is one of extreme gravity. Some authorities of weight, after prolonged investigation and research, have declared that the disease is never recovered from spontaneously. This is the accepted view of urologists, and the exceptions are of such rarity of occurrence that effective treatment can only be based upon the assumption that it is invariably true. There are some patients who, whilst incapable of eradicating the disease completely, yet localise the infection; the kidney is destroyed and replaced by a fibro-lipomatous mass containing encapsuled and inactive foci of bacilli, so that to all intents and purposes a nephrectomy has been performed. Such people may live to the end of their lives without any further sign of urinary tuberculosis appearing. Tuberculin therapy has been thought to contribute to this happy result, but success occurs too seldom for vaccine therapy to be considered preferable to surgery except under unusual circumstances.

As a rule, the diagnosis of unilateral renal tuberculosis demands nephrectomy without undue delay. It is therefore essential that diagnosis should take place early in the course of the disease and be capable of establishment beyond doubt. The discovery of tubercle bacilli in the urine alone may not be sufficient evidence, for Lüdhe and Kielleuthner were able to prove the excretion of bacilli by the uninfected kidneys of phthisical patients. H. Wildbolz maintains that in such cases the bacilli are so few in number that they are demonstrable only by guinea-pig injections, never by direct film examination. An essential finding in the urine is pus, or perhaps, in the earliest stages, endothelial or renal epithelial cells. "Aseptic" pyuria is characteristic of a tuberculous kidney. On the other hand, the collection of urine containing pus and tubercle bacilli from a kidney by means of the ureteric catheter does not always mean an infection of that kidney, for there may be an ascending ureteritis which has not reached the kidney, spreading across the bladder from the opposite ureter. This ureteritis, like secondary tuberculous cystitis, shows a tendency to spontaneous cure when the primarily diseased kidney has been removed. It therefore happens that some continental authorities do not lay stress upon ureteric catheterisation, and for the demonstration of the condition of the supposed healthy kidney consider it to be attended by danger and therefore contra-indicated; for a small abrasion of the ureteric mucosa

¹ The Effect of Lead on Red Blood Cells, *Medical Science*, vol. xi., No. 1, October, 1924.

caused by the catheter may allow of the implantation of bacilli, and so lead to the ascending infection referred to by Mr. C. A. R. Nitch in this issue of THE LANCET, an unfortunate result which may not become evident until some months after the cystoscopic intervention. These surgeons are inclined to pay great attention to the delay in the excretion of indigo-carmin as an index of disease of the kidney, and prefer to avoid altogether ureteral catheterisation.

The outlook after nephrectomy has been fairly well established by numbers of observers. About 60 per cent. of patients are cured. These results are improved somewhat, as Mr. Nitch has demonstrated, if the whole ureter is removed at the primary operation, whilst the mortality of the procedure is not increased thereby. Precautions should be taken not to infect the operation wound from the cut surface of the ureteral stump, and as much as possible of the perinephric tissues should be removed as they often harbour tubercle bacilli. The kidney should never be incised to verify a diagnosis, which can be made more certainly by previous investigations. Of recent years attention has been given to the possibility of affording relief by surgery to patients suffering from bilateral disease. Whether the more affected kidney should be removed or not is a question still sub judice. Eugen Joseph¹ recommends removal in bilateral cases of a closed pyonephrosis when the other kidney, by chromoscopy, appears to be only slightly injured, and he quotes one patient as living in health seven years later. Wildbolz² thinks intervention in bilateral disease is very seldom indicated, for the relief from pain and frequency afforded by the operation is only of short duration, the patient soon suffering as much as before. E. S. Judd and A. J. Scholl³ give the results in 18 bilateral cases; four died of uræmia after the operation and ten died during the succeeding 18 months. The results of operation upon bilateral cases should be scrutinised critically to be certain that the patients actually suffered from disease on both sides. Braasch, in 7 of 22 apparently bilateral cases, was able to prove by animal inoculation that bacilli were coming from the healthy side, and considered that such kidneys were infected. But, as we have seen, this may not be evidence of actual disease of the kidney, and the inclusion of such cases in statistics of bilateral cases may lead to error.

THE ODYSSEY OF FAT IN THE BODY.

THE importance of fatty foods and the rôle played by fat in the human and animal organism justifies the extent and variety of the researches into its absorption and assimilation. Apart from its great value as a source of energy arising from its oxidation into carbon dioxide and water, the amount and uses of the water so produced—the water so produced being greater in amount than the fat itself—has for some, and perhaps for all animals, a profound significance. The uses of this "metabolic water," as it is called by Dr. S. M. Babcock, are especially evident in hibernating animals and in those like the camel living for long periods in nearly waterless regions. Fat occupies a unique position amongst the food materials in the blood, for all except the fats are in solution; the major part of the fat, as soon as it passes through the wall of the intestine, appears in the lacteal vessels as a very fine emulsion—which has been termed the molecular basis of the chyle. The particles of this emulsion—the chylomicrons of S. H. Gage⁴—are mostly from $\frac{1}{2}\mu$ to 1μ in diameter and can be seen with great clearness and certainty by the dark-field microscope and can in that way be followed in the lacteals to the thoracic duct; and finally into the blood-stream and in the blood throughout the entire body. By the use of two non-poisonous red dyes—Sudan III. and scarlet red—which stain fat and which cling to its fatty acids through all the digestive changes, we have

been enabled to follow the odyssey of fat in the body—to trace its rebuilding when absorbed, and to chart its entire journey until finally the pink colour indicates where the fat is laid down in the body during the process of assimilation. The pink colour of the emulsion is visible in the lacteals, in the serum of the blood as well as in the fat reservoirs, and shows exactly where the fat is stored.

Experiments were made by Dr. Gage and Dr. Fish on healthy students who volunteered, as well as on cats, dogs, fowls, and rats. Healthy men and animals were fed with fat coloured red and mixed with carbohydrate food and in many cases protein was added, and every hour a drop of blood was taken and examined by the dark-field microscope during the digestive cycle. Neither protein nor carbohydrates, nor any combination of them give rise to fine particles in the blood. Fatty food is the only kind of food that gives rise to the emulsion of these fine particles in the chyle and blood. That the particles were fatty was determined by specific tests. The time after eating fatty food for the particles to appear in the blood is from one-half to one and a half hours. The time required for a given kind and quantity of fat to be digested, absorbed, and to disappear from the blood in any given individual or animal varies from about six to ten hours, but mental conditions were found to influence digestion. Whenever fat is present in any proportion, as in an ordinary meal, the blood of the man or animal shows a gradually increasing number of the fine particles for the first three to four hours, and a decline similar to the increase for the next few hours, till in eight to ten hours the blood is again practically free from the particles. Under normal conditions there is no increase of fat particles in the blood unless fat is taken with the food. The digestibility of castor oil was tested. After fasting from 12 to 20 hours 20 g. of castor oil were used with bread or potato, and a mineral oil (nujol) was similarly used. In both cases there was no increase in the chylomicrons, and it was concluded that there was no digestion of either substance. There was no purgative action until after the usual period for the digestion of fatty food. If a mineral oil is mixed with butter and eaten the butter-fat is picked out, digested and absorbed, and the mineral oil left behind. It takes a markedly longer time to digest and absorb fatty acids than ordinary fats. In a well-nourished man, after prolonged fasting, the remobilised fat appears in the blood as an emulsion of fine particles, comparable with those following the digestion of fat. It would seem that fat passes into the blood from the fat reservoirs as it is needed and at the rate it is needed. The dyes used attach themselves to the fatty acid part of the fat and not at all to the glycerol. As showing the persistence with which the dye clings to and remains with the fatty-acid radical after quitting the living animal, is the fact that if the eggs with red fat in the yolk are hatched, the chicks will utilise it and lay it down as pink fat in their reservoirs, and young mammals sucking the pink milk of mothers fed with red fat will digest the same and lay it down in their bodies as pink fat. In man the average time of a digestive cycle for fat is from seven to nine hours for 20 g. of butter.

This staining method can be used for studying the source of the fatty constituent of milk. Milk-fat in different groups of animals may be derived from different sources. In the cow and other almost purely herbivorous animals it is supplied most largely by the carbohydrates and proteins of the food. It is certainly only in a small degree due to the fat in the food. With carnivorous and omnivorous animals in which fat forms a relatively important place in the natural diet, the milk-fat is derived largely from the fat in the food—i.e., the fatty-acid radicals eaten with the food go to make up the milk-fat. By feeding rats and cats with Sudan-stained fat, pink milk was obtained, but on feeding cows with an abundance of the Sudan dye in the regular feeds, no pink cream was ever obtained from the samples of milk taken at every milking. Moreover, if laying hens are fed with Sudan dye

¹ Kystoscopische Technik, Berlin, 1923.

in their food, the fat laid down in the yolk will be red, and if several feedings are given and the eggs boiled and cut across, there will be as many rings of the red yolk as there were feedings. In the domestic fowl the yolk contains about one-third of its weight of fat, and this fat is derived largely from the fat in the food. By the use of coloured fat as a label in the yolk one can tell exactly how long it requires for one of the smallest yellow yolks to reach full size, break from the ovary, enter the oviduct, and have added to its outside the white, the shell membranes, the shell, and be laid. For a hen laying every day it requires from seven to eight days. The stained fat in the yolk does not diffuse its stains into the neighbouring uncoloured fat particles. If hens' eggs with pink yolk are hatched the developing chicks, in utilising the fats, lay down pink fat in their fat reservoirs. If a mammal like a rat, while nursing its young, is given red fat with its food, the young rats fed on the pink milk will lay down pink fat in their adipose tissue. The main absorption of fat from the intestine is from the middle part of the small intestine—i.e., from the jejunum and the first part of the ileum. In rats, cats, and dogs fed on pink fat, pink-coloured fat begins to be laid down first in the peri-renal fat and in the omentum and mesentery; it appears lost in the popliteal, the orbital, and the epidural fat masses. In half-grown rats known to have a good supply of red fat in their adipose tissue and fed on a fat-free diet, it took about 20 days for the pink fat to disappear. This method makes it possible to determine whether a given fat or oil is at all digested and absorbed and to what extent; and in diseased conditions the dark-field microscope demonstrates with great certainty whether fatty food is digested, absorbed, and assimilated.

THE REBUILDING OF MIDDLESEX HOSPITAL.

AT its last meeting the Court of Governors of the Middlesex Hospital was called upon to consider an important communication from its Chairman, Prince Arthur of Connaught, who left England on a visit to India a few days before the meeting was held. For some time past it has been evident that certain portions of the old buildings were far from satisfactory, and as a result of an exhaustive survey conducted by the hospital architect in consultation with the then President of the R.I.B.A. and the district surveyor, two wards were closed. A complete examination of the whole of the old hospital buildings disclosed evidence that the fabric would have to be reconstructed at a cost of at least £60,000, and the question at once arose whether it would be justifiable to spend such a large sum on what at the best could only be the postponing of the rebuilding of the old hospital fabric, which had already stood for over 150 years, was not well adapted to modern requirements, and was so planned as to impede future development. The board decided to adopt a rebuilding scheme involving an expenditure of at least £500,000. Steps have been taken to ensure continuity, and the old Sick Asylum in Cleveland-street is being reconditioned as an annexe, where patients, displaced from the old buildings, will be accommodated. Meantime the wards in the old hospital structure have been rendered safe with timber strutting. The cancer charity, medical school, and research departments are in no way affected by the scheme, and during the transitional period, treatment, medical education, and research work will be carried on exactly as now.

THE DANGERS OF THYROID MEDICATION FOR THE OBESE.

RECENT research has taught us that obesity may depend on many different factors. It may be the outward and visible sign of the vices of sloth and gluttony, and as such it is apt to excite ridicule without pity. But it may also be the expression of a morbid condition, acquired or hereditary, over which the patient has no control; he cannot choose his diseases any more than he can choose his parents. The causes, therefore,

of obesity being varied, it behoves us to elucidate them in each case before we prescribe treatment. It is, perhaps, unfortunate as well as fortunate that we possess in thyroid extracts the means of reducing weight in most cases of obesity, whatever the cause. A panacea may be a very dangerous thing. This is the lesson which Dr. E. Mosler, of the Third Medical Clinic of the University of Berlin, drives home with some vigorous plain speaking in the *Deutsche medizinische Wochenschrift* for Dec. 12th. He writes with the exasperation of the physician who, having treated a number of patients carefully for many years, sees them go to some fashionable institution for the treatment of constitutional diseases, whence they return with slender figures and the well-defined clinical picture of thyroid intoxication. Dr. Mosler gives an account of six cases, observed during the last few months, in which the administration of thyroid extracts, given by the mouth or by injection, did great harm. He had known these patients for years and had withheld treatment by thyroid extracts because he had considered the chief cause of their obesity to be over-feeding. The treatment of such patients is, indeed, a delicate psychological problem. The physician of to-day is confronted by an embarrassing choice. He may think, and if he is rash he may say so to the patient, that his or her obesity reflects more credit on the skill of the cook than on the alimentary austerity of the diner. The difficulties which Dr. Mosler discusses are only a part of a larger problem which recent advances in medicine have made acute. The discovery of insulin and other potent agents in the metabolism of the body has created a very widespread impression that years of sinning against the laws of health may be atoned for with a few injections of an extract of some endocrine gland. There have been times in the history of the spiritual world when it was generally taught that the misdeeds of a life-time could be suddenly neutralised by the judicious employment of appropriate incantations, and at the present time this optimistic tendency to trust to the short cut to reform is very manifest in the world of medicine. Dr. Mosler's aspersions on the conduct of private hospitals will not, we believe, find any general echo in this country, but in his discussion of the dangers of wholesale thyroid medication he has undoubtedly given prominence to a danger which is not confined to Germany.

PULMONARY INFECTION WITH VINCENT'S ORGANISMS.

Dr. Clyde McNeill,¹ of the Medical Clinic of the Halstead Hospital, Kansas, remarks that the spirochaetes and fusiform bacilli of Vincent are widely distributed throughout the entire world, and have been known to cause a great variety of lesions in the human body, including infections of the skin, external ear, middle ear, gums, mouth, throat, gastro-intestinal tract, trachea, and bronchi. He now records a case of pulmonary infection with these organisms, of which no previous example to his knowledge has been reported in the literature. The disease was clinically and bacteriologically indistinguishable from pulmonary tuberculosis, but was easily diagnosed by a stained smear of the sputum, and cleared up like magic under treatment by intravenous injections of salvarsan. Dr. McNeill's patient was a man, aged 36, who on admission to hospital had been suffering for two months from progressively increasing weakness, loss of weight, constant cough with muco-purulent sputum, epigastric discomfort, and occasional attacks of diarrhoea or constipation. There was no trace of ulceration or inflammatory changes of any kind in the mouth or pharynx. There was diminution of resonance over the upper third of both lungs anteriorly and posteriorly with intensification of the whispered and spoken voice, and there were a few moist râles at the apices after coughing. X rays showed areas of consolidation of varying intensity in the parenchyma of

¹ Bulletin of the Johns Hopkins Hospital, November, 1924.

the lung involving both upper lobes and presenting a striking similarity to the lesions seen in advanced active pulmonary tuberculosis. When the sputum was examined several hours after collection various bacteria were found, but no fusiform bacilli or spirochaetes. When it was examined one to two hours after collection a few spirochaetes were found but no fusiform bacilli, but immediately after it was coughed up it was found to be an almost pure emulsion of spirochaetes and fusiform bacilli. The patient was treated by intravenous injections of neoarsphenamin, the first dose consisting of 0.6 g. and the next three of 0.9 g. on each occasion. After the second injection the general malaise, cough, expectoration, pulmonary consolidation, and gastro-intestinal symptoms disappeared. The patient gained 32 lb. and was hard at work two months later.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CIII.—THE TREATMENT OF CARBUNCLES.

A CARBUNCLE is due to a molecular necrosis of the subcutaneous tissue, the result of infection with the *Staphylococcus aureus* or, in about 10 per cent. of cases, with the *Streptococcus pyogenes*. Little liquefaction of the necrosed tissue takes place and healing can only occur after the large central slough has been extruded. Carbuncles occur only in debilitated patients, and are a frequent complication of constitutional disease such as diabetes. The aims of treatment can be divided into two main classes—general and local. General treatment must be directed at (1) increasing the patient's resistance to the spread of infection, (2) elimination of toxins, (3) the production of sleep. Local treatment must secure (1) the relief of pain, (2) the removal of all necrotic tissue, (3) the arrest of infection in the surrounding parts, (4) epithelialisation of the raw surface after separation of the slough.

General Measures.—The patient's resistance to infection is increased in proportion to the degree of control of any constitutional disease from which he may be suffering; his general strength must be kept up by judicious feeding, the feeds being light, nourishing, and given at intervals of two hours. Eggs and milk should be the staple articles of diet. In cases where the patient's resistance is much lowered resource should be had to blood transfusion as an initial step in treatment. Vaccine treatment in severe staphylococcal infections is disappointing, often resulting in a temporary depression of the patient's resistance; for this reason vaccine and serum therapy is not advised in the acute stage of the disease, although small doses of an autogenous vaccine sometimes produce benefit in the later and chronic stages. Elimination of toxins is accomplished by flushing out the kidneys and bowels and promoting gentle secretion from the skin. Treatment is started by a saline purge and the bowels must be kept open each day by an adequate dose of salts; where there is evidence of intestinal decomposition small doses of calomel, gr. $\frac{1}{4}$ hourly up to gr. 1, should be given for three days. Large quantities of fluid, lemonade, barley-water, or "imperial drink," must be taken; a gallon a day is not too much. Finally, where the patient is well enough he must have a warm bath once or twice a day, or failing this a blanket bath. Sleep must be obtained at all costs. Where pain is the predominant factor in keeping the patient awake an adequate dose of morphia should be given.

Local treatment may be operative or non-operative, but in all cases immediate steps should be taken to give the patient as much relief as possible while other arrangements are being made. The affected part should be kept at rest, as every movement causes pain; where a limb is involved it should be placed on a splint. A wide area around the carbuncle should be shaved and cleansed thoroughly with soap and water or ether,

and then large fomentations made by wringing out several layers of boric lint in boiling water should be applied to the inflamed area and covered with jaconet and a thick layer of cotton-wool. Fomentations should be changed at half-hourly intervals except when the carbuncle is situated in such a position as to necessitate moving the patient and causing him undue discomfort.

Operative Treatment.

This should be looked upon as an emergency operation; a delay of 24 hours or more so that the patient may be "properly prepared" entails a great deal of unnecessary suffering and intoxication. The enema is the only stage of the routine preparation that need be taken. A general anaesthetic, not simple gas, should be given, so that the operator may have ample time to attend to the details of his task and may secure the dressings in position before the patient comes round. When the patient is anaesthetised any further shaving that may be necessary is done and the operation area thoroughly cleansed with ether. It is better to avoid the use of any coloured antiseptic such as iodine or picric acid at this stage as the extent of inflammation in the skin may be masked by the stain. There are two main operations practised for carbuncle: total excision of the diseased tissue by a circular cut, and incision. The latter is the method of choice in the majority of cases. An incision is made extending throughout the whole length and depth of the diseased tissue; a second similar incision is made crossing the centre of the original incision at right angles to its course. Four triangular flaps are thus mapped out covering the whole extent of the carbuncle. Each flap is raised in turn and all necrotic tissue is removed with sharp scissors, so that a fresh bleeding surface is left on the inside of the flaps and on the base of the operation area. Oozing may be controlled by packing tightly for two minutes with gauze wrung out in hot saline. Where there is intractable bleeding it is best dealt with by touching the bleeding points with the actual cautery, and for this purpose there is no better instrument than an ordinary soldering iron.

When all hæmorrhage has been controlled the wound is packed with gauze soaked in a concentrated solution of magnesium sulphate; jaconet and then a thick layer of absorbent wool are applied and the patient returned to bed. The dressing must be changed at the end of 24 hours and after that will probably require renewing twice a day. The advantage of the magnesium sulphate dressing is that it promotes a free flow of serum which tends to wash out toxins from the wound and to limit the spread of infection. Healing appears to be more rapid with this than with any other method. Its great disadvantage is that it requires frequent changing.

An alternative to the magnesium sulphate dressing is bipp. A little bipp is taken on a piece of gauze and rubbed firmly into the walls of the wound, all excess of ointment is sponged away and the cavity packed lightly with gauze. This dressing may be left in position for two or three days and then renewed under gas.

A popular method of treating the wound after removal of the slough is by cauterisation with carbolic acid. Each of the four flaps is held back with a tissue forceps and then a tiny gauze mop is taken in a pair of pressure forceps and dipped in liquid carbolic acid. This is dabbed over the walls of the cavity, care being taken to avoid the skin edge. The cavity is then sponged dry and packed with gauze. It is claimed for this method that it arrests all hæmorrhage and kills off any organisms that may have been left behind after the excision of tissue. Also that carbolic acts as a local anaesthetic and the patient is spared much pain after the operation. The disadvantages of the carbolic treatment are that the new sloughs take a long time to separate and healing is correspondingly retarded. Again, if carbolic be applied over a large surface there is some risk of carbolism from absorption. As an alternative to carbolic acid, fuming nitric acid has been employed, but it has little to recommend it.

After-treatment.

All first dressings should be performed under gas anaesthesia. The gauze dressing should be soaked before being removed and then the wound cleansed by irrigation with saline, eusol, or hydrogen peroxide (4 vols.). In replacing the packing care must be taken that the edges of the wound are packed well open and are not allowed to become undermined. The skin around the wound should be well cleaned at each dressing with ether; this minimises the risk of infection of the neighbouring hair follicles, with the formation of a crop of boils. Too much emphasis cannot be laid on the importance of keeping "the injured part at rest" whether by splinting or sand bags. Should it be found at any time that carbuncle formation is continuing in the edge of the wound the diseased area must be completely excised at a second operation. After excision of a carbuncle the wound ultimately heals by granulation, epithelialisation taking place from the edge. Where there is a large surface to be covered the process may be considerably hurried by the use of the Thiersch graft or by secondary suture.

Non-operative Treatment.

The most successful method of treating carbuncles without operation is that devised by the late A. E. Morrison and is dependent on the brisk flow of serum induced from the tissues around the carbuncle by the application of a paste of magnesium sulphate. The following was his method of preparing the paste: "With 1½ lb. of dried magnesium sulphate are mixed 11 oz. of glycerine acid, carbolic, and pure glycerine. The dried magnesium sulphate is in the form of a white powder which contains 12 per cent. less water than the ordinary commercial Epsom salts. The glycerine is put in a hot mortar and the sulphate added, the paste being slowly stirred and mixed with a warm pestle. The result is a thick white cream, so hygroscopic that if exposed to the air it rapidly absorbs moisture and becomes fluid. It must therefore be preserved in a covered jar." The area round the carbuncle is shaved, cleansed with ether, and carefully dried. A thick layer of the paste is spread on a piece of lint and this is applied directly to the carbuncle and surrounding skin. The lint is covered by a piece of jaconet and then by abundant cotton-wool. A profuse discharge of serum is induced and it is generally necessary to change the dressing twice in 24 hours. There is great relief of pain after the first or second dressing, and in the majority of cases the central slough separates in a few days. In the meantime, with the discharge of serum, toxic symptoms are considerably abated, the temperature falls, there is less headache, and the patient feels generally better.

After separation of the slough Morrison recommended packing the cavity with strips of sterile lint wrung out in a saturated solution of magnesium sulphate to which glycerine had been added in the proportion of 5 oz. to the pint. The subsequent treatment is the same as that employed after operation. The one great advantage of this treatment is that an operation is avoided. Against this are the facts that it is slower and more uncertain than operative measures. It should be reserved for those patients who refuse operation or who are unsuitable subjects for a general anaesthetic.

"Malignant" Carbuncles.

Carbuncles situated on the nose, or on the surrounding part of the face, so frequently prove fatal that the term "malignant" has been applied to them. Infection from them is prone to travel through the angular vein and its connexions into the skull and cause cavernous sinus thrombosis. Radical operative measures should always be applied from the first in dealing with "malignant" carbuncle even if the plastic surgeon be required to complete the treatment.

Surgeon to the Albert Dock Hospital; Senior Demonstrator of Anatomy, St. Bartholomew's Hospital Medical School.

Medicine and the Law.

REX v. BATEMAN.

BEFORE MR. JUSTICE SHEARMAN at the Central Criminal Court, on Friday, Dec. 12th, 1924.

Counsel for the Prosecution: MR. PERCIVAL CLARKE, MR. H. D. ROOME, and MR. J. D. PURCHASE (instructed by the Director of Prosecutions). Counsel for the Prisoner: SIR EDWARD MARSHALL-HALL, K.C., and MR. ARTHUR DAVIES (instructed by Messrs. Amery Parkes and Co.).

Readers need no reminding that the charge here was that Dr. Percy Bateman, during conduct of a labour, had caused the death or accelerated the death of a patient by failure to call in a second medical practitioner and to arrange for an immediate operation. Sir Bernard Spilsbury, for the Crown, intimated that if the woman had been operated upon she might have survived, and that she would have been a fit subject for operation before her final removal to hospital, where she died. Dr. Bright Banister, obstetric physician to Charing Cross Hospital, and Dr. Hubert Roberts, obstetric physician to Queen Charlotte's Hospital, gave evidence for the defence, as did the defendant himself. Dr. Banister stated that in his opinion immediate removal to hospital would have destroyed any chances of survival and that he could see no evidence that any more favourable time for removal could have been selected, a point on which the practitioner must be the judge.¹ Dr. Roberts said that the woman was in acute danger from shock and a major operation would have been inadvisable.

The Judge's Summing-up.

The verbatim report of the summing-up of Mr. Justice Shearman follows:—

MR. JUSTICE SHEARMAN. Members of the Jury, this is a tragic case. It has been argued, and you have heard the evidence of very eminent people, and I am glad you heard it because it is a matter which demands your most anxious consideration, and I am sure will receive it. The charge against this man, who is a member of the medical profession, is that he by gross negligence has caused the death, or, if he has not caused it, has accelerated the death of a woman. It is a serious charge and I think you quite understand it. Although we are dealing with matters that laymen find it difficult to understand, I think some of you have been in the jury-box before and understand this, that the function of the judge is to explain the law to you, and also, to the best of his ability, marshal the facts and put them in detail to you, but the sole question as to what inferences are to be drawn from the facts which you find to be true and how far you believe or trust one witness rather than another, is entirely for you. I will endeavour to do my part of the matter, and I am sure you will do yours.

I want first of all to explain the law to you. The law is that anybody who causes the death of anybody else—it does not only apply to a doctor, it applies to motor drivers, railwaymen, or signalmen—it applies to a number of people—anybody causing the death of anybody else is criminally responsible. It is equally clear law that no one is criminally responsible for what I call, making a mere mistake, and it is really for the jury to draw the line between what is called making a mere mistake, an error of judgment, and doing something which is grossly and palpably wrong. I have only one objection to make to the law as put before you by the Counsel for the defence: that a man is bound to do to the best of such skill as he has. That is not quite accurate. A medical man who practises for profit the medical profession professes skill; he does not come and say: I am an unskilled person—he is engaged and

¹ See p. 51.—ED. L.

professes skill. Of course, you will understand it is not for every humble man of the profession to have all that great skill of the great man in Harley-street; but, on the other hand, they are not allowed to practise medicine in this country unless they have acquired a certain amount of skill; they are bound to show a reasonable amount of skill according to the circumstances of the case, and you have to judge them on the basis that they are skilled men, but not necessarily so skilled as more skilful men in the profession, and you can only convict them criminally if in your judgment they fall below the standard of skill which is the least qualification which any doctor should have. You should only convict a doctor of causing a death by negligence if you think he did something which no reasonably skilled doctor should have done. You have got to consider if this man in anything he did fell below the level which you expect of a doctor—below that degree of skill which you think you have the right to expect of a doctor—by no means the extreme skill which everybody knows of, but that degree of skill which you expect from a doctor who attends an accouchement and who is taken to know his business. There is one other thing about the law I have to say, and that is, some doctors at times have to deal with people who are very ill and are bound to die, and it is no good to say: "Oh, I gave the wrong physic, but she would have died afterwards"; and I shall leave it to the Jury to say whether the death was caused or accelerated by the treatment administered. In adopting the word "accelerated" you have got to act with great caution. It really means this: That you think by the treatment the patient died when otherwise she would not have died substantially at the time she did. You will consider carefully, and it is only right that you should consider carefully: Well, if he had done something else she would have lived a day longer, and whatever her chance was, her chance of living was taken away by his attitude. You will apply that test. That is all the law I will explain to you.

Members of the Jury, I want to shortly go through the evidence, because this, as I say, is an anxious case for all concerned. You must neither neglect the case of the woman nor neglect the interests of a man in an honourable profession; he is being tried criminally and alleged to be the cause of her death. This woman was the wife of a poor man, a builder's labourer. She had had four children and was acquainted with the pangs of childbirth. She expected her fifth child in the third week in July and she had provisionally engaged the services of a midwife. She had had pains on the Monday and they passed off in the afternoon and you may think, it is entirely for you, that she knew she was not going to be delivered at once because she was experienced. At any rate neither she nor her mother sent for the midwife. She had pains on the Tuesday and they passed off in the afternoon. It is said by the defence that these were three days of labour, and it is said by the prosecution these were ordinary preliminary pains. On Wednesday labour came on and in the afternoon she sent for the midwife. The midwife she had engaged could not come and the lady you heard yesterday afternoon came. It is entirely for you, you have seen the witness, and if she is to be belittled I am a little astonished because she gave evidence in favour of the defence. She said she had had over 30 years' experience, and she said she came in the afternoon before the doctor came in, and that if this delivery had gone off properly no doctor would have been sent for at all. She was there to assist the lady and she said she put her hand outside the stomach and she felt the living child. She also said in cross-examination that she did put her finger in and she felt, she thought, the symptoms of a head. In ordinary delivery a child comes through the womb either head first or feet first; either of them are proper modes of delivery. Putting her finger in she felt the head and for some time, more than an hour, nothing happened and the pains continued and she said: This is beyond me, I will send for a doctor,

and she asked the mother herself who she wanted, and Dr. Bateman was mentioned, and Dr. Bateman was eventually sent for, and some time after 10 o'clock in the evening he arrived. While I am dealing with her evidence let us recollect this, that what is called the vagina is the entry into the womb; what is called the uterus is the womb. The uterus itself is a species of bag with a mouth which is fastened, because the mouth down below is firmly fixed to the flesh; it is itself a sort of bag with muscles and full of blood-vessels and it is fastened at the top and sides with what are called broad ligaments. The doctor came in and took his coat off. When he found two other people in the room prepared to assist at this childbirth besides the midwife he, admittedly quite properly, ordered them out of the room. The midwife had dressed this woman in her nightdress and skirt, which is usual for childbirth. The woman was put on the bed and the doctor began to work away and the child would not come. It is admitted he worked away with her, and according to his account in the letter, he had to use great violence or great force. Do not take the "violence" against him, it means "great force." He worked at this for an hour. There is one thing, of course, you will notice, and that is that during the whole of the time the midwife was there; she was looking on and assisting, and she makes no complaint of his violence or force. You will bear that in mind, and that is why I wondered that this lady's evidence was attacked and they tried to say she was not able, when her evidence is for the defence, which is, of course, that there was nothing done by him in that room which was to her, as a midwife, anything that was improper. He worked for an hour and the child came out dead. During the whole of the time, and this is the evidence of the midwife, blood was flowing freely and the child was produced. Let me pass on till we come to the post-mortem to find out what really did happen. Because all the four doctors, the doctors called for the prosecution and the defence, happen to agree on a theory, that is no reason why you should accept it, but it may make you ready to accept it when you find the competing authorities agree. No one disputes that the bladder was ruptured and that there was a rupture of at least two inches. No one disputes that, the intestines being crushed against the sacral bone which comes near there, there was a wound in the intestines as well only done by pushing; at some time or another I should have mentioned that the doctor used instruments for a minute and then stopped, and he gave them up, and no one suggests any harm was done by the use of instruments. For about an hour he was pushing the child, this being what is called a difficult presentation, and at any rate the foetus or small baby was cross-wise across the womb, if nothing worse. "Transverse," as you know, means "across," and it should come head downwards or feet downwards and the proper business is to turn it and get it out. It would appear that during the course of the hour's work that this man gave to procure the childbirth the womb was broken, ruptured, and injury was done to the bladder, and injury was done to the intestines, and he produced the child dead. When he had produced the child dead the woman then was in a state of collapse; she had been bleeding freely and that was noticeable to him and the midwife as well, but the midwife does not recollect that he gave her some strychnine in order to revive her. She says she does not recollect it, but the doctor says he did. That is the midwife's account. I will give you the account of what happened after the child was produced; it was a full-time child. She says this: "Then he went for the placenta." That is a Latin word—it is a kind of membranous stuff which is in the habit, if things go all right, of coming out itself—or it is also called the afterbirth. "He delivered the child; he tied the cord and separated the child and I took it away and put it on the bed. He went for the placenta. This was going to be put into the chamber"—which she afterwards called a vessel. "I saw him remove the

placenta; he pulled it out sharply. I handed him the vessel to put it in. There had been a considerable flow of blood and after the placenta was taken away the bleeding ceased to a certain extent and Mrs. Harding seemed very feeble. After the placenta had been brought away the doctor said, 'Leave her in bed, she is very low and very feeble,' and then he got ready to go and I asked him to examine the placenta before he went and I put it on a chair. I looked at it and I did not know what it was. I said, 'What is this? I never saw anything like that before'; he said, 'Good God, what have I done?' I said, 'I do not know, what is it?'; he said, 'Do not you know?' and he then told me it was the uterus. I said, 'Surely not,' and he said, 'Whatever shall I do?' I said, 'I do not know,' and he removed the placenta and he said, 'Give me something to wrap it up in and I will take it away.' He put it in his bag and took it away. I asked him if he did not think the poor woman ought to go away. That expression is always used, and it means to be taken to the hospital, because you know that with these poor people the Harley-street or second opinion, or more skilful opinion, is obtained at the hospital and not by calling in an expensive doctor to give another opinion. He then washed his hands and went away. She remained a little while. She does not say in this court that the doctor told her not to say anything, but he admits that he told her not to say anything, and he says it was because "I thought the woman was going to die and I did not want to shock the relatives by letting them know what had happened." The woman was left in bed and the mother-in-law and sister-in-law came in the room. The woman was put on her side in bed and the midwife and doctor went away and she was left there and neither came back till the next morning.

That is the whole of the evidence with regard to what is called the first part of the case. It is said that this man so treated her that by his treatment he committed all these injuries, he ruptured the womb, he ruptured her bladder in pushing about, and he caused the injuries to her intestines; and in the same way it is said that when he came to pull out the placenta instead of pulling the placenta out of the womb he caught hold, not of the placenta, but of some tear or slit in the torn womb and with a tug, the expression was "a sharp pull," he pulled it away. It is said by the Crown that that shows that in doing this, and in pulling out the womb, he was guilty of gross negligence. It is said on behalf of the defence, and they called eminent surgeons—it is said on behalf of the defence: Well, the nurse saw nothing wrong with the way he treated her although the force was used and necessary, and it was unfortunate. It is said there was no gross negligence, and it is for you, if you feel any doubt, to see that the prisoner gets the benefit of the doubt, but are you satisfied on that that there was gross negligence? The doctors called for the defence say this; they say "Oh, it is quite reasonable to mistake a tear in a womb for the placenta." That is entirely a matter for you, and it is a view not entirely accepted by the doctors called for the prosecution, although they agree in cross-examination that after all this working a portion of the womb might be torn, but a reasonably skilful man might know the difference between pulling a womb and something that might be adherent to the inside, and the prosecution call attention to the fact of the steady outflow of blood and say that in pulling out the womb he was guilty of gross negligence, and the defence say, a very natural mistake in the circumstances of the case. The witnesses called for the Crown took this view; they took the view that the pulling out of this was a matter which people ought to see; and the witnesses for the defence take the view it is natural, there is no gross negligence, at any rate it is quite a natural thing under all the circumstances of this difficult presentation to make a mistake. Dr. Spilsbury said it would want some considerable force, whatever happens, to pull away the womb; it came away with one ovary and one tube attached to it. It was said by Dr. Spilsbury there must have been some considerable force to get

it away, and the defence say it might easily come away if there was some damage done before.

Let me pass on to the second question. The Crown first of all say there was gross negligence, and you will not find it unless you are quite satisfied of it, in pulling away the womb at all—in what he did before and in pulling it away. It is suggested by the defence nothing of the sort, at most and at worst it was a very difficult case, and at most and at worst it was a mistake, and we say it was not negligence, it was the sort of thing that might happen in this remarkable case. It is admitted that the coming away of the womb in the case of a child-birth is almost unknown. Dr. Spilsbury in his wide experience has only heard of it twice, and the doctor who was in charge of Queen Charlotte Hospital said: "I have had under my charge 60,000 cases and I have never heard of such a case," and the other witness said he had not heard of such a case. Dr. Spilsbury said when it has happened before, in his experience the child has died at once.

MR. DAVIES. Dr. Banister said he had two cases.

MR. JUSTICE SHEARMAN. I think he said as regards turning the womb inside out; certainly at the hospital he said there had been no case, but at any rate it does not matter whether they heard of one or two cases, it is an extremely rare case, and one of those cases where the experts differ. As you know, expert witnesses who come are called to say they have read the evidence and give their views and give their evidence on their instructions. Dr. Spilsbury for the Crown says this is what is called a transverse presentation and until evidence was given before the Coroner, in the letter and in the evidence given by the nurse, it was never said this was a difficult case—it is a transverse presentation, which means cross-wise. When this man gave evidence before the Coroner he made it much clearer that it was what is called a complex case, and that it was what is described as a transverse presentation. In ordinary language transverse means cross-wise, and he means the whole thing was doubled up. When you find differences in expert witnesses you must remember the Crown witnesses were giving evidence on the assumption that this was a transverse presentation and the whole of the evidence for the defence was given on the assumption that the child was doubled up in the way you saw the rubber doll doubled up. If you think it was not transverse at all you may consider that it weakens the evidence for the Crown, but on the other hand the evidence for the defence is considerably weakened if you believe it was given on the basis that there had not been one day's labour but three days, and, secondly, that the presentation, such as it was, was this extraordinary and difficult presentation of head and feet together when it is said the child was dead. The Crown say that is not true, that the child was evidently alive, and if the child had been all this time with its head and feet together it could not be alive, and that that story given at the inquest or to the expert witnesses at all events is not accurate.

Passing away from that and summing-up the first case, if you think and are quite satisfied that it was his treatment in tearing away the womb—previous to and up to tearing away the womb—you will convict him; if you are not satisfied and think there was no negligence at all, or if you have a reasonable doubt whether there was gross and culpable negligence up to that point, you will acquit him. Then this man went away, and let me trace the doctor's movements. He went away and came back the next morning and he never examined or did anything to the broken ligaments or the broken blood-vessels. The womb had gone and there were there injuries which he knew nothing about, and I daresay they could only be discovered by examination, but he did nothing. Afterwards he came twice every day and I think he sent a sleeping draught and came and called to inquire how she was. On the first day he called he saw the witness Miss Lehoux, I think it was, and he said "How is she?" and she said, "She is getting on." "Oh, that is very funny," he said, because he was surprised she was alive; and to another witness on the Friday, Mrs. Barwick, he said, "I am surprised to hear she is

still alive." He came again on the Saturday and on the Sunday and on the Monday, and on the Monday or the Sunday night the nurse came to see him and the nurse said, "Ought not this poor woman to go away to hospital," and he said, "I will see about it." Eventually three times during the course of the day somebody went round to the house and left messages for him, and finally, at 5 o'clock, he made an order for her removal, but before we get to the removal let us see what the other witnesses say, because there is a conflict of evidence which you have to decide. The nurse is not in the place all the time; she goes away. She knew what had happened; she knew the womb had gone; she was the only other person who did know. She came the next morning and she saw this patient once a day. Her view was that this woman was slowly and gradually collapsing; she never was any better. That was the nurse's view. On the other hand, that is not the view of the members of the family. This is the husband's account of it anyhow—I am mentioning this on the question of whether removal was possible or not; the husband said, "On Friday she was very weak and she continually vomited"—that is agreed—"that she did not keep anything down." Dr. Spilsbury's reason was: He said there was paralysis of the bowels; they were unsupported and she was paralysed; the other witnesses say it was not paralysis, but I do not know that it matters very much, but the witnesses say she could not eat anything. "On Friday she was bright, but still weak and vomiting." They say on the Sunday morning in the daytime she was much brighter, but night came on and she became worse and she had bad pains on Sunday night, and it may be that was the peritonitis, which is inflammation of the coating of the stomach, and she got worse and she was in continuous pain all the Sunday night. That is roughly the evidence. The doctor may have said, "I am surprised she did not die; I expected her to die at the time." But in the meantime from that time to this he had done nothing to her; he had sent her Epsom salts to try and clear her bowels and they were immediately ejected—she could hold nothing and there was nothing done by local injection. The case presented by the Crown is this; they say when once this womb was torn away there were broken blood-vessels, or whatever they are, and there may have been no flowing of blood afterwards because this poor woman's circulation was nearly gone and it may have been that these veins tend to clot and they do not go on bleeding. What is said by Dr. Spilsbury is this; he says here was the womb out and there was nothing to support the pelvic floor, and the intestines must drop as soon as she got up, and something had got to be done to see that the bowels were kept from prolapsing, which means falling down, and to see that these wounds which had been bleeding were in some way sewn up or fastened so that there was a chance of her recovery; and Dr. Spilsbury particularly says unless something was done recovery was hopeless—unless this floor was "restored," was, I think, his expression. He said there must have been death unless the floor was restored. All these experts I say are giving evidence on facts put before them; they were not present and did not see the woman. He says as soon as she rallied sufficiently from the state of collapse she ought to have been fit for an operation. What is said by the Crown is that what this man has done is this: That he knew he had pulled away something; and whether he was guilty of gross negligence in his conduct up to that time of pulling out the womb is a question for you, but knowing he had done it he was guilty of gross dereliction of duty in doing nothing for her thinking she would die, and she would not have died when she did if something had been done for her; and it is for you to say whether what he did in taking away the womb and telling nobody about it, not treating her in any way and not sending her off to the hospital, was because he thought he would avoid inquiry into his previous conduct by letting this woman die

of neglect. That, substantially, is the case for the Crown on the second part of the case, and they say substantially he was guilty of grave wicked neglect and culpable neglect of duty in not taking some steps to remedy what had been done by his own fault, or if you do not think it was gross negligence they say he ought to have done something to try and save this woman's life, but he did not do anything because he wished to save his own reputation.

That is the case for the Crown. The case for the defence is admittedly she was very weakened: "I could not get Harley Street to help me; I did not take her to the hospital because she was up four flights of stairs and it would have killed her to take her down." It is admitted that she was taken away four or five days afterwards; she was taken away and lived for something like 30 hours after she went from there to the hospital on Monday morning and she died very late on Tuesday night. She lived 30 hours after she had gone, and if on the Thursday or Friday she had gone they might have done something to save her life; but the case for the prosecution is: You did nothing and accelerated her death at the time it was caused. If you have a doubt the prisoner gets the benefit. The case for the defence is: This was hopeless and the only thing to do was to leave her quietly to die instead of taking her to the hospital and that he thought the best thing was to let her die and leave her where she was. The experts for the defence agree it would have been a good thing to try something in the nature of drainage, but an operation was hopeless. But they had not seen the woman, nor had Dr. Spilsbury, and they are only giving such advice on the material put before them. The material put before them is that the woman was very weak, and it is said she was rallying a bit on Friday up to the Sunday morning and something ought to have been done. What is clear, and that you will have to bear in mind, is that admittedly she had not a very good chance once the womb was removed. But the case for the Crown on the second part of the case, which it is for the Crown to prove to your satisfaction, is that owing to the breach of duty in concealing the fact and not letting anybody do anything to help her, not communicating with the hospital, doing nothing, and it is suggested with an expectation that she would die, he substantially accelerated her death and took away any chance this woman had of being saved or having her life prolonged by an operation. Whether she could have had an operation and what was her state of body and health depends on the inferences you draw.

Let me pass on to what evidence there is from this man himself. When he did send her to the hospital his view was she would die at once if sent. Admittedly she got very much worse on the Sunday evening. The nurse sees him on the Monday, and on the Monday afternoon sends a letter, and this letter runs as follows: "Dear Dr. Wiggins"—we only saw his assistant Dr. Buchanan—"Dear Dr. Wiggins, I was sent for on Wednesday last by a midwife to attend a Mrs. Harding, of 25, Norfolk House, Deptford; she had been in labour for over two days; the labour was transverse"—you notice there is not a word about it being doubled up; I will say something about that again later—"I delivered her after considerable trouble. On extracting the placenta I found to my surprise that the uterus came with it." I will hand this letter to you, you are the judges of it. It is said that was not a candid letter. It is said a certain impression would be given to the doctor—for the placenta to come away with the uterus is an almost unheard of thing—and that the meaning of those words is that he extracted the uterus and put it in again. This is his story: "Evidently the uterus had been expelled into the pelvic cavity sometime previously and the uterus had contracted firmly on the placenta; she was very collapsed"; and then comes this remarkable statement: "She has been doing fairly well until the present but is now in a bad way and cannot be looked after at home. I am therefore sending her to the infirmary." If that means anything it means "I thought she would recover at home, but now she has got worse and I am sending her

to the infirmary." It is said it is not the real truth, but he was trying to keep something back. You are not trying the question of whether he was keeping something back, but whether he was guilty of gross negligence. The woman was taken to the hospital. She was very bad when she got there but she was conscious. On the Tuesday she was becoming rapidly unconscious. She lingered till about 2 A.M. on the Tuesday night and she died. Then there was inquiry made and there was a post-mortem examination. The matter was brought before the Coroner about a week afterwards. This man was not summoned before the Coroner, but a message was sent by the Coroner's Officer that there was going to be an inquest on this woman and he went, and the uterus was asked for, and he said he had got it and went back for it; there were some snips at the side of it and he gave the explanation that when he took it home he thought of this extraordinary thing and he cut it up to see what it was and there was nothing. Those are the historical facts. Do you think, assuming you are satisfied by the prosecution that in pulling away the womb at all and the acts preceding, that he was guilty of gross negligence and culpable negligence in causing her death?

Then you come to the second head: Was he guilty of gross or culpable negligence in accelerating this woman's death by so neglecting her from the time that he knew her uterus had been removed? If you are quite satisfied that the woman wanted treatment and, from the history of the case, that if she had had some treatment her life would have been prolonged, you will find him guilty; if you have any doubt about it you will find him not guilty. I will remind you of what I said to you at the outset, that you have to be satisfied, not only that he was guilty of gross and culpable negligence, but that he caused or accelerated her death; and there again is this difficulty, and you have to weigh it, that Dr. Spilsbury says that in his view her life would have been prolonged and she had a reasonable chance, not a strong chance, of surviving, if those tears and wounds had been attended to and the danger of blood poisoning by septic poisoning had been attended to by treatment. Even the doctors for the defence admit, although they do not say it was culpable negligence, that if there had been some effort to drain—an operation, they say, was impossible from their view by the facts put before them—if something had been done—(there was urine coming through—there was a crack or small hole in the intestines and stuff was coming through and was likely to cause the peritonitis which afterwards ensued)—it would have been better. There is only one other matter, and you have to be satisfied before you convict the prisoner, and that is the evidence he gave before the Coroner. It runs as follows, and I will hand it over to you: "I was called to see the deceased on Wednesday, July 23rd, shortly after 10 P.M. I found her in labour and was informed that she had had pains for two days previously. I could feel the head quite easily. I gave chloroform and applied instruments; they slipped at once." Then he adds this: "It was a transverse position, the feet, head, and cord were all presenting together." There is no hint of that in his letter; there is no hint until he comes before the Coroner. It is said by the Crown when he is on his defence and he is called to explain that, then he is giving a different account to what he gave before. The account he gave then was: "It was not, strictly speaking, a transverse presentation, it was head and feet together," what one of the doctors said was a complex presentation, and then he says, "Immediately I put my hand into the vagina I found a foot. I had great difficulty in turning the body because the child was outside the uterus; it was in the pelvic cavity; it had been expelled into the pelvic cavity." Everybody agrees now, his experts and himself, that when he says "When I put on the instruments I did get hold of the head, but I maintain that the child was in the pelvic cavity and outside the uterus at that time"—I do not want to go into the difficulties as to what is meant by the

pelvic cavity, because I think it is now admitted by the defendant and his witnesses that obviously he was wrong in that statement; and, of course, the fact that he put up a statement or defence which is wrong makes you scrutinise more closely his conduct, but it does not necessarily prove because he made a mistake in his account of it that he was guilty of gross negligence in what he did. Then he goes on to say: "When I first saw the patient she was not collapsed." Then he says: "I found it difficult to push the head back because it was outside the uterus but eventually I did deliver her after being under chloroform for at least an hour, feet first by manual traction. I had to use tremendous violence. I had to wring my shirt when I went to bed, I had sweated so much over the job. It was the hardest case I have ever had. After delivering the child I extracted the placenta immediately. It was in the uterus, it came away quite easily. The room was badly lit at the time and the mother was practically dead at the time. I placed the placenta and what I thought was the membranes hurriedly in the chamber and attended to the mother in order to save her life. I felt the woman's pulse and found it was absent. I gave her a hypodermic injection of strychnine after which she rallied slightly. Both Mrs. Cleak and I placed our hands over the abdomen to see if the uterus was contracting and to our surprise we could not find the uterus. Mrs. Cleak then brought me the chamber and I found that the uterus was there and the placenta was inside the uterus which had thoroughly contracted over it. Therefore when I saw what had happened I did not want to shock the relatives and I told her (Mrs. Cleak) to say nothing about it." So that only about a fortnight afterwards he then did not present the same story which he presents here, that this was not strictly a transverse presentation but it was this head and feet presentation which caused so much difficulty, and which is admittedly the most difficult of all the presentations, and almost unknown in the history of childbirth, and which is very, very rare at any rate. I give that to you at the last because it again presents his case as it is put here, and his case as put here is this. He says: "I concealed the fact that the uterus was taken away. I said in this letter the uterus was away and I told the hospital authorities that on the Monday, but I did it for the best. The motive, the reason, I left her there was I thought if I took her away she might die; it would kill her on the spot to take her away—and therefore it was a legitimate exercise of my opinion to let her stop there." It is said by the Crown: Nothing of the sort, he should have done something, and the reason he left her there unattended to was to save his reputation and not to save or benefit the patient.

That is the whole case. If you are satisfied that either in the way he delivered the child or in the way he acted afterwards he acted with gross negligence and thereby caused her death, you will find him guilty; if you are not satisfied you must acquit him on that part of the case. If you think after the womb had come away his conduct and neglect of her substantially accelerated the date of her death—if you are quite satisfied of that you will convict him on that part of the case. If you feel any reasonable doubt on either theory you will give him the benefit of the doubt and acquit him. Will you please retire and consider your verdict?

(The jury retired at 4.5 and returned into Court at 5.15, a bailiff being sworn to take charge of the jury.)

THE CLERK OF THE COURT. Members of the jury, have you agreed upon your verdict; do you find the prisoner, Percy Bateman, guilty or not guilty on this indictment?

THE FOREMAN OF THE JURY. Guilty, my Lord.

THE CLERK OF THE COURT. You say that he is guilty and that is the verdict of you all?

THE FOREMAN. It is.

Mr. JUSTICE SHEARMAN. Have you anything you want to say, Mr. Davies? There is nothing against this man: there is no justification for calling the police or anything of that sort?

Mr. DAVIES. I feel the agony of this verdict is sufficient and nothing I can say will—

Mr. JUSTICE SHEARMAN. I appreciate what a serious thing a conviction is. I hope nobody will think I treat a charge like this with levity in giving a short sentence. I appreciate with a professional man what a crushing blow a conviction is itself, and the sentence of the Court is six months imprisonment in the Second Division.

Special Articles.

INFECTIOUS DISEASES ABROAD.

THE following general summary is compiled from the monthly Epidemiological Reports published by the Health Section of the League of Nations, supplemented, when possible, by more recent information from other sources.

Plague.—The most important occurrences since the issue of the last summary¹ are a new outbreak in the Azores and the apparent cessation of the outbreaks at Lagos (Nigeria) and Los Angeles (California). In the Azores the locality affected is about three miles from Ponta Delgada, the chief port of the island of St. Michael. Eight deaths were reported during the week ended Dec. 12th. The epidemic at Lagos, which began at the end of July and attained its maximum during the week ended Oct. 13th, is reported to have ceased in the second week of December. The total cases notified during the epidemic were 406 and the deaths 337. In the Los Angeles outbreak² the pneumonic cases apparently ceased during the week ended Nov. 5th, but they were followed by several cases of bubonic type. The latest information available, dated Dec. 6th, reports one new case of bubonic type from the area originally infected. Other recent occurrences in different parts of the world were: United States, one case at New Orleans week ended Dec. 9th; Brazil, two cases at Bahia week ended Dec. 11th; Peru, 24 cases during October, of which 14 occurred at the port of Lima; Egypt, one case at Port Said week ended Dec. 2nd; Algiers, three cases during November; Senegal (French West Africa), 161 cases between August 11th and Sept. 10th; Union of South Africa, in four States or Provinces between Oct. 7th and Dec. 4th 24 cases, of which 20 in the Cape of Good Hope Province were reported to be of pneumonic type.

Cholera.—In India as a whole the curve of cholera incidence for the year began to slope downwards after August and is now approaching its lowest level, but it is evident that when the total figures of cases and deaths for the present year are known, they will greatly exceed those of 1923 and 1922. Outside India there are very few cases at present.

Yellow Fever.—The cessation of yellow fever in the Republic of Salvador was officially notified on Nov. 13th, when 19 days had elapsed since the last reported case in Ahuachapan and 29 days since the last case in San Salvador City. Measures for the reduction of *Stegomyia fasciata* have been prosecuted energetically for several months and it is now considered that the risk of spread has ceased. In British Honduras three cases, one being fatal, were notified between Nov. 18th and 22nd in a locality 19 miles west of the port Stann Creek. The colony was officially declared free on Dec. 12th.

Typhus.—There has been no noteworthy change in the incidence of typhus in the various countries of Eastern Europe since the issue of the last summary. At Constantinople between Nov. 9th and Dec. 6th five cases with one death were notified.

Small-pox.—The small-pox situation remains favourable in nearly all European countries. In Switzerland the cases notified up to the end of November this year numbered only 1226 as compared with 2119 during the same period last year. No case was notified during the week ended Nov. 29th. In Spain the epidemic, which had caused over 900 cases in Madrid and neighbouring towns during the three months from August to October, was officially reported on Nov. 14th to be at an end. Jugo-Slavia was free from the disease from July to the end of October, but in November a new outbreak occurred in Bosnia-Herzegovina.

Enteric Fever.—The usual autumn wave of enteric fever is obvious in the monthly returns from most countries and is more pronounced in several countries than it was last year, particularly, for example, in Sweden, Finland, Poland, Czecho-Slovakia, Hungary, and Bulgaria. In Germany enteric fever was more prevalent during the whole summer than in 1923 or 1922, but the incidence declined rapidly after the middle of September. In Italy the incidence during September and October compared favourably with the incidence during those months of 1923.

Scarlet Fever and Diphtheria.—The increased prevalence of these diseases continues in Germany and Poland, but in the Balkans the situation is more favourable than last year. The following are some recent statistics of deaths in certain European cities: Paris, Nov. 20th to 30th, four deaths from diphtheria, four deaths from scarlet fever; Berlin, week ended Nov. 22nd, three deaths from diphtheria, one death from scarlet fever; Warsaw, week ended Nov. 22nd, three deaths from diphtheria, ten from scarlet fever; Copenhagen, week ended Nov. 22nd, two deaths from diphtheria, one death from scarlet fever; Vienna, week ended Oct. 11th, three deaths from diphtheria, one death from scarlet fever.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

The Minister of Local Government and Women Doctors in Asylums.

THE Ministry of Local Government and Public Health appears to have been unfortunate in the drafting of a letter sent recently to the committee of management of the Grangegorman Mental Hospital, in reference to the filling of a vacancy among the medical officers of the Portrane Branch. According to the reports of the meeting of the committee, as given in the daily press, instructions were received that as regards medical officerships only men were to be appointed, although the vacancy was due to the resignation of a woman doctor. When questioned on the matter in the Dail, Mr. Burke, Minister of Local Government, stated that his letter gave no general order as to future appointments, but was a particular order dealing only with the existing situation. At the present time, he said, in Portrane Mental Asylum there were two lady medical officers, and there had been considerable indiscipline amongst the male patients of the asylum, and it was considered desirable that a male doctor should be appointed to the next vacancy in order to get over that difficulty.

The Woman Medical Officer's View.

The Minister's explanation might have been considered adequate if the duties of the officer to be appointed were on the male side of the asylum. That this is not so is made clear by a letter from Dr. Kathleen Meade, the medical officer who has

¹ THE LANCET, Dec. 6th, 1924, p. 1198.

² THE LANCET, Dec. 13th, 1924, p. 1251.

just resigned. The letter was published in the daily papers, and stated:—

"I note that the Minister said: 'It is quite obvious that where male patients have got out of hand it is more desirable that a male medical officer should be appointed to deal with them.' To avoid the misunderstanding that may arise from this statement, perhaps you would allow me to point out that my duties at Portrane since my appointment comprise the charge of the female patients and female staff, and relief duty for the male medical officer who has charge of the male patients and male staff, the latter only being emergency medical attendance. The question of 'discipline' amongst the male patients was not within my province."

"As the vacancy occurs on the female medical staff, it should be obvious that, in the interests of the public and the patients, a woman medical officer ought now be appointed."

It looks as if the Minister of Local Government were trying to escape from a false position into which he had been led by some of the more reactionary members of his staff. It is well, however, that he was tackled on the subject at once, as it would be deplorable if any obstructive policy on the part of his department were to interfere with the employment of women doctors in asylums.

Payment of Asylum Medical Officers.

It is not only in regard to the employment of women doctors in asylums that the Ministry of Local Government is tending toward a reactionary policy. In the same letter to the Grangeogorman Committee as was mentioned above, it was laid down that future appointments to assistant medical officerships should be made at a salary of £300 without allowances for a period of two years' probation. At the end of that time the salary should be increased by £50 a year. The chairman of the committee pointed out that if such a salary were adopted, the medical officer would be paid less than the head attendant. The resident medical superintendent added that it would be impossible to go to the medical profession with such a proposal, as the pay would be less than that given to the carpenter. It does not appear whether the Ministry thinks that the discipline which it so much desires would be promoted by making the tradesmen superior to the medical officers.

Queen's University, Belfast.

Sir William Whitla was appointed a Pro-Chancellor of Queen's University, in place of the late Sir Samuel Dill, at a meeting of the Senate on Dec. 23rd. Sir William Whitla resigned his active duties as professor of materia medica and therapeutics a few years ago, and was then elected to represent the University in Parliament, when the ability which he had shown in the science and practice of medicine became equally evident in his work as a politician.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

Is Nervous Disorder Blameworthy?

I HAVE been asked by a prominent Edinburgh citizen whose work, though he is not a doctor, brings him in contact with nervous disorder, why it is that in Scotland such disorders—hysteria and the like—and even definite insanity are regarded in some way as criminal or as highly blameworthy. His point is this, and I give it as far as possible in his own words:—

"I have known one case of suicide from this cause. The victim's relatives could not rid themselves of this notion, and though they were affectionate in their behaviour, they nevertheless conveyed the idea to the unfortunate patient of being a guilty encumbrance upon the earth. To take a less serious example, I have heard a man who spent three years on the Western Front complain bitterly of the contempt with which certain persons at home treated him when his nerves finally broke down. Another individual who had suffered from several severe attacks of depression and had been treated with considerable injustice both by his near relatives and business acquaintances, finally decided

to emigrate from the country in the hopes of finding a more humane atmosphere elsewhere. Cases also occur where an organic incurable disease is treated as a mere nervous symptom which could be got rid of by an effort of the will. It seems to be certain that in melancholic cases the condemnation of relatives and of the world is a confirmation of the patient's own condemnation of himself and exerts an enormous pressure against him. Such persons often behave in public, it is true, in an excited manner and give the impression of conceit, when they are in fact only in a state of extreme morbid anxiety and depression."

"The cases I have mentioned occurred in Scotland, where the effect of the severe Calvinist religion still lingers. The Sheriff-Substitute of Ross and Cromarty at Stornoway, in Lewis (i.e., the county court judge) stated in letters to the *Scotsman* some months ago that religious melancholia is more frequent in Lewis than in the other islands of the Outer Hebrides whose inhabitants are Catholics, and I have heard this opinion confirmed by a doctor who had made some investigations into lunacy in these islands. In England, life is more humane and civilised than in Scotland, owing to the gentler type of religion and the long period in which tradition and culture have had the opportunity of development, and it is possible that such cases as those I have mentioned are in comparison with Scotland less frequent. In glancing at the literature on this subject I have not noticed many references to the effect of the hostile attitude of the world upon the nervous or the mentally diseased, except in Clouston's 'Hygiene of Mind.'"

My informant, further, is of opinion that much might be done by the medical profession to create a more humane and intelligent public opinion. He feels that condemnation has a demoralising and even fatal effect in alienating the victim from the world, whereas respect and consideration have the opposite effect. In the Middle Ages the insane were flogged. He considers that the treatment which the mentally disordered often receive nowadays is less violent, but essentially no less brutal.

St. Andrews Institute for Clinical Research.

The work at the Institute, St. Andrews, for the spring term will deal with various aspects of the question of renal efficiency. The meetings are held in the Institute on Tuesdays at 4 P.M., and the syllabus promises an interesting series of papers and discussions. The subjects for discussion during January are the following: Metabolism with special reference to the Kidney, on which Prof. E. P. Cathcart, of Glasgow, will read a paper; the Eye and the Kidney, a lantern demonstration by Dr. Maitland Ramsay; the Clinical Application of Tests for Renal Efficiency (Prof. Adam Patrick). On Thursday, Jan. 22nd, Prof. F. J. Charteris will give a demonstration of kidney cases in his wards in the Royal Infirmary, Dundee, and a meeting of the Association for Clinical Investigation will be held in the Royal Infirmary, Edinburgh, on Saturday, Jan. 31st. All practitioners are cordially invited to all meetings of the Institute.

Edinburgh University Extensions.

At a recent meeting of the Edinburgh University Court, the Principal, Sir J. Alfred Ewing, announced that substantial donations had been recently made to the University in response to repeated appeals. At the time of the graduation of the Prince of Wales last month it was announced that Sir Alexander Grant had made a gift of £50,000, and more recently other donors have given sums amounting to £16,600. Much more, however, is still required to allow the most urgent wants to be met. It was decided to proceed at once with the scheme for the alteration and extension of the department of surgery in connexion with the grants recently received from the Rockefeller Foundation for the development of clinical teaching and research.

Royal Infirmary, Edinburgh: Retiral of Mr. Alexander Miles.

At a meeting of the Edinburgh Royal Infirmary on Dec. 22nd, at which the Lord Provost presided, the retiral on Dec. 31st, 1924, of Mr. Alexander Miles, senior surgeon to the infirmary, was announced, in accordance with the infirmary regulations as to tenure

of office. Mr. Miles was appointed house surgeon to the Royal Infirmary in 1889, his chief being Mr. Alexander G. Miller, now the doyen of the surgical profession in Edinburgh. Ten years later he became assistant surgeon and in 1910 was promoted to the rank of surgeon, his retirement at the present time marking a milestone of 15 years' service in the wards. The board expressed their gratitude for Mr. Miles's services by asking him to allow his name to be placed on the roll of consulting surgeons, and in the minute which embodied this request a sincere tribute was paid to his professional judgment and skill. Mr. Miles, in conjunction with the late Prof. Alexis Thomson, was the author of one of the best known text-books produced by the Edinburgh School of Surgery, and wrote an admirable monograph on the history of the school. For many years he was surgical editor of the *Edinburgh Medical Journal*.

Glasgow Western Infirmary Jubilee.

At the annual Christmas meeting of the friends of the infirmary and members of the staff, Colonel J. A. Roxburgh, Chairman of the Board of Managers, announced in his report that the financial position of the infirmary was in a more satisfactory position than it had ever been at any other period of its history. Colonel Roxburgh said that 50 years ago last month the Western Infirmary had opened its doors for the reception of patients, and since 1874-75, when the number of indoor patients was 1253, the infirmary had been growing in usefulness and in accommodation. In the first year the number of outdoor consultations was 5916, while last year it was 149,325. The wards in the original building numbered eight, to-day the number of wards was 32. Originally intended as the clinical school for the University on its then new site at Gilmorehill, the infirmary had throughout its history maintained a close connexion with the University, and the Regius Professor of Medicine and the Regius Professor of Surgery still conducted their clinical teaching in the wards of the Western. The Western Infirmary was one of the earliest hospitals in the country to start an X ray department and this had been in active operation for a number of years. In the research department the progress from the small room in which Dr. Coates began the work in 1875 had been almost beyond belief had they not the splendid buildings of the pathological institute and the clinical laboratory and the work done in them as a reminder of the strides made in this connexion within the last half century. One of the latest additions had been the massage and electrical department which was now a recognised school for training. The teaching of nurses had also of late years been very much developed and rendered more efficient. With regard to finance the Chairman said that although the ordinary income had never been wholly adequate, yet it was encouraging to note the way in which the employees in the public works had within the last few years come to recognise their responsibility in the matter of helping the various charitable institutions carried on for their benefit. Although the finances for 1924 were satisfactory, nevertheless the gap between ordinary expenditure and ordinary income still remained very wide.

New Operation Theatre for the Royal Infirmary, Montrose.

At a recent meeting of the board of the infirmary a resolution was passed permitting the erection of a new operation theatre at an estimated cost of £17,000, and to devote £500 donated to the infirmary by Sir James Warwick, of Edinburgh, and also part of £2500 bequeathed by the late Mr. W. Slogie, of Montrose, for this purpose. At the same meeting it was announced that the late Mrs. McCay, of Londonderry, a native of Montrose and daughter of the late Adam Burnes, a well-known Montrose solicitor, had left the residue of her estate to Montrose Infirmary, Londonderry Infirmary, and St. Dunstan's Hospital. The sum bequeathed to the Montrose Infirmary is understood to be considerable.

SOUTH AFRICA.

(FROM OUR OWN CORRESPONDENTS.)

Public Health Congress.

DELEGATES from all over the Union of South Africa gathered on Nov. 24th at the Scientific and Technical Club, Johannesburg, for the second annual Public Health Conference. Dr. Ernest Hill, the medical officer of health, East London, presided, and many interesting communications were made.

Municipal Milk Control.

Durban is at the present time in the throes of controversy over the new draft Milk By-laws. The dairy-keepers declare that these by-laws will bring their ruin, and contend with some reason that the milk-supply of Durban is not inferior to any in the world. The whole subject of milk control was dealt with by Dr. S. J. Clegg, formerly deputy M.O.H. for Newcastle-on-Tyne and now M.O.H. for Durban, at the Johannesburg Congress. The dairy inspector, Dr. Clegg contends, is not to be regarded as a policeman. The sanitary conditions of Natal are good, and the milk by-laws in South Africa generally already in advance of those in force in England and Wales. Everything turns on the firm and sympathetic administration of these by-laws. Medical opinion at the Congress was, on the whole, in favour of pasteurisation, although recognising the value of raw milk.

Plague in South Africa.

A conference on plague, called by the Minister of Health of the Union of South Africa, was held at Bloemfontein on Nov. 13th under the presidency of the Minister of Health, the Hon. D. F. Malan.

The Minister, in his opening address, recalled that it was over 20 years since plague had been first introduced into South Africa, and referred to the fact that in India since its reintroduction in 1896 11 millions of persons had perished from the disease in that country. The Government had decided to increase their grant to the South African Institute for Medical Research with a view to further research on the subject, and to equip a mobile field laboratory. The elevator system of handling grain was proving a blessing in this connexion, but a year or two would elapse before it was in full operation. Dr. J. Alexander Mitchell, Secretary for Public Health and Medical Officer of Health for the Union, reviewed the ætiology of plague, its history, and the present position of the disease in the country, giving a table of its regional and colour distribution for the last 24 years. In 1924 the districts concerned included Albert, Colesberg, Bloemfontein, Boshof, Brandfort, Bethulie, Hoopstad, Kronstad, Lindley, Senekal, Heilbron, Philippolis, Smithfield, Winburg, Wolmaranstad, and Krugersdorp. The incidence so far recorded this year was 51 whites with 27 deaths, and 303 coloured with 195 deaths. No definite evidence was obtained as to what agency was keeping the infection alive, but veld rodents were suspected. In 1920 an investigation into the rodents and small animals in the affected districts was begun by Mr. Austen Roberts, naturalist to the Pretoria Museum, and Mr. Powell, an expert tracker and trapper. In February, 1921, a farmer in the Kronstad district sickened and died of plague. He had been in the habit of taking a mid-day siesta under a clump of bush near his farm, and a large colony of gerbilles and multimammate mice were found close by this, thoroughly infected with plague, and several dead bodies of the animals were found on the surface of the ground. Since then the existence of widespread plague infection of veld rodents had been demonstrated. It was regarded as probable that the present outbreak was the result of the recrudescence of plague infection amongst wild rodents that had been acquired by them during the plague prevalence of 1900-05. The infection had been found most commonly in the gerbille, which was

a purely nocturnal animal, rarely seen by man, and rarely or never entering dwellings. The other animal principally affected was the multimammate mouse, which lived sometimes in gerbille burrows and sometimes in dwellings or outhouses, taking the place of the domestic mouse in these districts. The area in which the veld rodents were infected with plague measured 50,000 square miles. The growth of the rodent population had been greatly encouraged by the destruction of their natural enemies, the jackals, lynxes, and cats, the clearing of bush which used to harbour owls and hawks, and the great development of mealie growing. During the epizootic certain areas were kept free from rodents so as to form "plague fire-belts." These held good for a time, but later the infection spread around them.

Having set out the existing situation, Dr. Mitchell discussed future risks in regard to local spread, spread to the large towns, and spread overseas, and in the discussion after his address the main conclusions arrived at were the following: (1) That persistent and well-organised propaganda should be undertaken with a view to enlightening farmers and others as to the mode of spread of plague and the means of combating it. (2) That scientific research into the problem involved should be undertaken and subsidised. (3) That the number of expert rodent inspectors and demonstrators should be increased. (4) That all buildings should be made rat-proof, so as to "build out" the rodents. (5) That plague-carrying rodents on farms should be controlled and limited in numbers. (6) That the natural enemies of these rodents should be protected and fostered. (7) That by the use of grain elevators and the rat-proofing of grain stores precautions should be taken against conveying rodents from infected areas. (8) That vigilance committees should be formed in infected areas to institute and coördinate measures for dealing with plague and rodents.

The First Doctors Trained in the Transvaal.

Johannesburg has this year, for the first time, produced its own doctors. The medical students of the Witwatersrand University recently held their final examination, when the four successful candidates out of an entry of 13 were Messrs. B. I. Kany, L. Klein, G. F. Slade, and G. C. Thompson. It is understood that all these recently qualified men will shortly take up appointments at the Johannesburg General Hospital.

A dinner in honour of the Faculty of Medicine of the Witwatersrand University was given by the final year students at the Trocadero, Johannesburg, on Nov. 15th. Mr. C. Duthie presided, and among those present were Sir William Thomson (Principal of the University); Dr. A. J. Orenstein, President of the local branch of the British Medical Association; Prof. J. M. Watt, Dean of the Faculty of Medicine; and Dr. R. P. Mackenzie, superintendent of the General Hospital.

The Leprosy Committee.

The Minister of Public Health (Dr. Malan) has appointed a leprosy committee to consider and advise the Union Government regarding leprosy research and other matters relating to leprosy in the Union. The personnel of the committee is as follows: Dr. J. A. Mitchell (Secretary for Public Health and Chief Health Officer), chairman; Dr. W. Watkins Pitchford (Director, South African Institute for Medical Research, Johannesburg) or his deputy; Prof. A. W. Falconer (Professor of Medicine in the University of Cape Town); Prof. O. K. Williamson (Professor of Medicine in the University of the Witwatersrand); Dr. A. Pijper; Dr. F. C. Willmot (Assistant Government Health Officer); and Dr. G. W. Robertson (Government Pathologist).

Medical School for Natives.

At the last meeting of the Council of the South African Native Conference, held at Alice, Cape Province, the question of a medical school for natives

was discussed at some length. The principle of erecting such a school in connexion with the College has already been adopted and approved by the Union Government, and classes for the first year of the course will be opened in 1925. In this connexion the appointment of Mr. J. Macdonald, M.A., of Greenock, as lecturer in botany and zoology was confirmed.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

"Impregnation" by the First Husband.

A CURIOUS case of insanity which has recently occurred has started Parisians discussing a very old problem. A man married a widow by whom he had a son, and in this son the second husband found more and more points of similarity to the first husband who had been dead some five years before the child's birth. The idea that this child was born "impregnated" by the mother's first husband became fixed in the mind of the second husband, who spent his time comparing the gestures and features of this child with those of the alleged "impregnator." This retrospective and, as the Parisians call it, "uterine" jealousy, provoked its victim to acts of violence, necessitating curtailment of his personal liberty. Cases such as this are not unknown to alienists, and less interest attaches to the incident itself than to the discussions to which it has given rise. What, it may be asked, does even the average educated man of the middle classes know of the modern teachings about such matters? To put the matter crudely and concretely, what would a gentleman farmer say if a thoroughbred bitch were mated with a mongrel dog and a year later with a thoroughbred? Would he be able to say definitely whether the second litter would show no evidence of its mother's previous mesalliance? The fact of the matter is that the "knowledge" of the man in the street, not to mention the man in the country, is biblical and traditional rather than Mendelian in this matter.

Virisection Filmed.

Thanks to the initiative of Mr. Desvieux, who is on the Municipal Council, credits have been voted for the preparation of six educational films showing some of the lessons to be taught by vivisection. Recently one of these films was demonstrated by Dr. Laugier, Prof. Lapique's assistant, and the spectators collected in one of the amphitheatres of the Sorbonne followed with great interest a film showing a dog being operated on under a general anaesthetic. It is hoped that this and similar films will prove of considerable educational value to students of medicine, and that this device will *ipso facto* reduce the number of operations performed on animals for teaching purposes. A committee of physiologists has taken part in the preparations of these films, the technical details of which must have strained the ingenuity of even the best cinema experts. The first films will assuredly not prove to be technically perfect, and even when they become so, if this ever happens, it is doubtful if their teaching value will be great.

The Anti-venereal League.

A general meeting of the National League against Venereal Diseases was held recently in the large amphitheatre of the Faculty of Medicine in Paris. Mr. Le Beau, Councillor of State and Director of Public Hygiene, was in the chair, representing the Minister of Public Hygiene; representatives were also present for the Minister of War and the Cardinal Archbishop of Paris. Alongside Dr. Jeanselme, President of the League, were seated delegates from the French Red Cross, from the International League of the Red Cross, and from the International Union against Venereal Disease. Dr. Jeanselme outlined the work of the League during the past year, and Mr. Le Beau then detailed the present position of the

campaign in France. The financial credit accorded to the League was, he said, insufficient for the work it did. Dr. Queyrat gave a lecture on the organisation of the fight against syphilis, and the meeting concluded with a demonstration of a cinematographic film entitled Syphilis, the Social Scourge.

Communal Vitality.

It is laid down in French law that when the mortality-rate for any one commune exceeds for three consecutive years the average mortality-rate estimated for the whole of France, special steps must be taken to deal with factors causing such unsatisfactory state of local public health. Dr. René Martial pointed out recently to the Academy of Medicine that this formula was somewhat rudimentary, on the grounds that, even if there is a direct relationship between the mortality-rates and the health of a commune, this relationship may vary greatly, nor does it constitute the only indication of health conditions in the commune. In fact, the mortality-rate may be normal, whereas the actual conditions of life in the commune are very unhealthy. The health conditions of a commune should not, therefore, be assessed by the mortality-rate alone. The assessment should be based on a knowledge of the morbidity of the commune from the individual point of view as well as from the collective standpoint. This view-point gives due proportion to health and social aspects, and allows a proper appreciation of the vitality of the commune. Further, it is of great practical importance, as to reduce the mortality-rate—a relatively easy matter—is alone not enough. To this conception of the racial characteristics of the commune coupled with living conditions, Dr. Martial gives the name of communal vitality.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

Jubilee of the Deutsche Medicinische Wochenschrift.

THE *Deutsche Medicinische Wochenschrift*, commonly called *D.M.W.*, has recently celebrated the fiftieth anniversary of its birth. The journal was founded in 1874 by the late Dr. Börner, of Berlin, and from the beginning it differed from other journals of the time in that, apart from scientific articles, it dealt extensively with hygienic, social, and professional questions. When Dr. Börner died in 1885, his journal had already obtained a firm footing, and under his successor, Dr. Gutmann, its position was further strengthened by the fact that one of its most distinguished contributors was the late Prof. Koch, who contributed his fundamental articles on the tubercle bacillus, tuberculin, and the cholera bacillus in the *D.M.W.*; also the articles of Prof. v. Behring on the diphtheria bacillus and on diphtheria antitoxin appeared in that journal. Dr. Gutmann died in 1893, after eight years in the editorial chair, and his successor was the well-known Prof. Eulenburg, with Dr. Schwalbe, then a young man, as co-editor. Prof. Eulenburg retired from the *D.M.W.* in 1903 to devote himself exclusively to his great standard work, the "Realencyclopädie der gesammten Heilkunde," and Dr. Schwalbe is now sole editor. The works of Prof. Ehrlich on chemotherapy, of Prof. Wassermann on immunisation, and of Prof. Bier on regeneration appeared in the *D.M.W.*, where also the first Röntgen photograph of a hand was published in 1895. During the war the journal was thinned down to about half its former size—from 1352 pages per half-yearly volume to 778—but in the past five years the *D.M.W.* has regained its full vigour and will certainly continue to be one of the leading medical journals of the world. On the occasion of the jubilee a special number has been published, containing a history of the journal, together with articles written by leading medical men on the development of medicine and its branches and on the history of the medical profession in Germany during the past 50 years.

Juvenile Coronary Sclerosis.

Before the Berlin Medical Society Prof. Klemperer described a case of sclerosis of the coronary arteries in a girl, aged 13 years. In the history of the case measles, varicella, and an attack of hæmaturia five months previously were recorded. The patient was brought to hospital in September for dyspnoea, general debility, and sleeplessness: examination showed bilateral dilatation of the heart, murmurs at the mitral valve, swelling of the liver, oedema, and cyanosis. Slight albuminuria and cylindruria were stated to be present. After ten days the condition became suddenly worse, pericardial frictions were heard, and radiography revealed a pericardial effusion. Under cardiac tonics there was a temporary improvement only and the child died with increase of oedema, dyspnoea, and anuria. The post-mortem examination findings were somewhat surprising; there was a large hæmopericardium, caused by a rupture of the heart over the apex of the left ventricle which proved to be aneurysmal. The coronary arteries showed sclerosis and fatty degeneration of the intima, the lumen being obstructed by thrombosis. Sclerosis was further present in the aorta, the subclavian and the carotid arteries and in the arteries of the brain. Cases of arterio-sclerosis in children have been observed in a few instances as an accidental symptom, but the special feature of this case was that the sclerosis of the coronary arteries was primary and had led to a rupture of the left ventricle.

The Battle of the Clubs.

While the battle of the clubs described in these columns has come definitely to an end in the greater part of Germany with the retention of the free-choice system, in Berlin the position is only that of an armistice. Notwithstanding this armistice, the Berlin clubs continue to take measures which are detrimental to the interests of the profession. They have established surgeries of their own and pretend that these surgeries are more comfortable, in a better hygienic condition, and better provided with modern apparatus than the consulting-rooms which the medical men use to attend their club patients. In these surgeries the medical attendants are full-time medical officers appointed with a fixed salary, who by their contracts with the clubs have renounced the right of private practice. It is obviously the aim of the clubs to spread the system of surgeries owned by the clubs and worked by full-time medical officers, who in this way are totally dependent on the goodwill of the club boards. The medical profession have protested against these measures as being contrary to the terms of the armistice. They point out that it is not by new apparatus and lavishly furnished consulting and waiting rooms that a patient is cured but by the skill of the medical attendant. Proceedings before a court of arbitration have not given a decisive result and the Government has kept a neutral attitude toward that important question. At a great protest meeting held in the town-hall of Berlin, in the presence of representatives of the Government, the medical faculties of the German universities, and the leading medical societies, a resolution was passed that the independence of the medical profession was absolutely necessary for the welfare of the nation.

Death of Prof. Trendelenburg.

The death is announced of Friedrich Trendelenburg, one of the most celebrated surgeons of the old school in Germany. He was born in 1844 in Berlin, a son of the renowned professor of philosophy at the university, who was a fervent antagonist of Hegel's doctrine. He studied medicine in Berlin and on qualification he went for post-graduate study to Glasgow and to Edinburgh. He then became an assistant to the great surgeon, Prof. Langenbeck, in Berlin, and in 1874 was appointed chief surgeon to the newly opened municipal Friedrichshain Hospital in the capital. Having held that office for one year only, he became ordinary professor of surgery at the

University of Rostock and then at Bonn. In 1895 he succeeded the late Prof. Thiersch as professor of surgery in Leipzig, where he lived until 1912. In that year he retired to his native city to enjoy there an *otium cum dignitate* in one of the fashionable suburbs. His work concerned operations on the larynx and the abdomen; the Trendelenburg tampon cannula devised by him to prevent blood from entering the lung after tracheotomy, and the Trendelenburg position for laparotomies will connect his name for ever with the great progress of surgical technique. Other works of his concerned operations for strictures of the oesophagus and cancer of the stomach. After his retirement from office he wrote a history of the German Surgical Association, of which he had been president, a work which was in fact a history of general surgery during the past 50 years.

NATIONAL HEALTH INSURANCE.

APPEALS FROM MINISTERIAL DECISIONS: THE NEW RULES.

PROVISIONAL rules have been drawn up by the Rule Committee of the Supreme Court for regulating appeals and references to the High Court under the National Health Insurance Act, 1924. The proposal involves the repeal of Rules 1-11, both inclusive, of Order LV, B and the substitution of the following rules and title:—

NATIONAL HEALTH INSURANCE ACT, 1924.

1. An appeal under Section 89 of the National Health Insurance Act, 1924, from a decision of the Minister of Health shall be instituted in the King's Bench Division of the High Court of Justice by originating notice of motion.

2. Any person who is aggrieved by, and is desirous of appealing against, a decision of the Minister of Health may, within 21 days from the date of the decision, or within such further time as the Minister may allow, by notice in writing addressed to the Minister, stating the grounds of his appeal, require the Minister to state a case setting forth the facts on which his decision was based, and his decision thereon, and the Minister shall, as soon as may be, state the case and send it by registered post to the person aggrieved. A case stated by the Minister shall be signed by him or by such person as he may authorise in that behalf.

3. An originating notice of motion shall be filed in the Crown Office at the Royal Courts of Justice within 21 days of the despatch of the case, or within such further time as the Court may allow, and the notice of motion shall at least 21 days before the time fixed by the notice for making the motion be served upon the Minister and, together with a copy of the case, upon every party to, or person served with notice of, the proceedings before the Minister. The notice of motion shall be in the form No. 18B set out in Part II. of Appendix B, and shall state the grounds of the appeal. The case shall be entered in a list to be kept at the Crown Office for that purpose.

4. Proceedings on a reference of a question under proviso (iii) to Section 89 (1) of the National Health Insurance Act, 1924, by the Minister of Health to the High Court for decision shall be instituted in the King's Bench Division by originating notice of motion in the form No. 18C set out in Part II. of Appendix B. The notice of motion shall be filed in the Crown Office at the Royal Courts of Justice and shall be entered in the list referred to in the last paragraph.

5. The Minister shall state the question referred by him to the Court, together with the facts relating thereto in a case stated and signed in the same manner as on an appeal.

6. The Minister shall serve the notice of motion, together with a copy of the case, upon the person or one of the persons as between whom and the Minister the question has arisen, at least 21 days before the time fixed by the notice for making the motion.

7. Upon the hearing of an appeal or reference the Court shall have power if it thinks fit to amend the case or to order the case to be sent back to the Minister for amendment or to receive further evidence.

8. The Court in all cases of appeals or references shall have power to draw inferences of fact from the facts set forth in

the case, and shall determine all questions arising thereon, and in all cases of appeals shall have power to reverse, affirm, or amend the decision appealed against or to make such other order as it may think fit, including any order as to costs.

9. The decision of the Court on an appeal or a reference shall be embodied in a certificate to be signed by the judge at the hearing and the original thereof shall be filed in the Crown Office and a copy thereof sent by the Crown Office to the Minister of Health and to the parties appearing at the hearing of the appeal or reference respectively.

10. The ordinary practice and rules of the King's Bench Division shall in so far as the same are applicable and are not inconsistent with this Part of this Order apply to proceedings under this Part of this Order.

11. Nothing in this Part of this Order shall be construed to affect any right vested in the Crown by virtue of the Royal Prerogative.

(New forms of notices of motion are set out in an appendix to take the place of the old forms 18B and 18C which are annulled.)

These Rules, which may be cited as the National Health Insurance (Procedure on Appeal) Provisional Rules, 1924, will come into operation as from Jan. 1st, 1925. The Rules are dated Dec. 16th, 1924, and are signed by Viscount Cave (Lord Chancellor), Baron Hewart (Lord Chief Justice), Sir Ernest Pollock (Master of the Rolls), Sir Henry Duke (President, P.D. & A. Division), Lord Justice Sargant, Mr. Justice Sankey, Mr. Justice Roche, Mr. Justice Lawrence, and the following well-known barristers, Mr. T. R. Hughes, Mr. E. W. Hansell, Mr. C. H. Morton, and Mr. Roger Gregory. They may be obtained from H.M. Stationery Office, price 1d.

ENCEPHALITIS LETHARGICA IN MANCHESTER.

Dr. W. St. C. McClure, of the Public Health Office, Manchester, has prepared a special report on this disease in Manchester during 1924. It attacks young people especially; the mortality is heavy, and in many of the survivors the disease is progressive and destructive. During the nine months ending Sept. 30th, 1924, 263 persons were reported to be suffering from this disease in Manchester, and 230—122 males and 108 females—after investigation were accepted as true cases. Persons of all ages were attacked, but the incidence fell most heavily upon those under the age of 21 years; 24 males and 19 females died. No particular occupation influenced the spread of the disease. This evidence obtained during this epidemic does not support the view that there is a direct association between an outbreak of influenza and this disease. As to the frequency of certain symptoms, vomiting occurred at the beginning of the illness in about 10 per cent. of the cases and headache in 36 per cent. Pronounced lethargy with or without nocturnal insomnia was present in 70 per cent. Insomnia and delirium without lethargy was a marked feature in about 30 per cent. of the cases. Paralysis of one or more cranial nerves occurred in 40 per cent. Double vision was complained of by 101 persons, or about 44 per cent. of the total, and in addition 18 persons complained of hazy vision. Nystagmus was noted in 10 per cent. Spasms and twitches occurred at the beginning of the illness in 31 per cent.; hiccup in eight cases. The outstanding feature of the epidemic was the frequency of diplopia as a symptom of onset. In a considerable number, diplopia and some drowsiness were the only symptoms displayed. Of the 230 cases, 102 were removed to Monsall Hospital, 60 were treated in other institutions, and 63 were nursed at home. The duration of stay in Monsall Hospital of non-fatal cases varied from 14 to 104 days, the average being 38 days. As to the sequelæ, it is too soon to determine the end-results of the illness upon those attacked during the present year. Of 55 survivors whose illness began at least six months ago, 19 have been recorded as totally incapacitated, 26 as partially incapacitated, and 10 as recovered. There were 50 cases in the years 1920-21. Of these, 28, or 56 per cent., died. Examination has recently been made of the 22 survivors, and it has been recorded that five were totally incapacitated, the disease rapidly progressing towards complete helplessness; four were able to do housework only, and 13 were able to follow their employment or attend school, though not all of them had completely recovered. Complete recovery was noted in seven cases.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH: A BRIEF SURVEY.

THE usual circular has been issued by the Ministry of Health with regard to these reports. The circular points out that the annual report for the year 1924 will be an ordinary report, but that the report for 1925 will be a survey report, in which the medical officer will be expected to deal comprehensively with the progress made in his area during the preceding five years, with the extent and character of the changes made during that period in the public health services of his area, and with any further action in the development of the public health services contemplated by the local authority or considered desirable by the medical officer himself.

We have commented at some length in previous issues on the reports of medical officers of health for 1923. This year was noteworthy both for the lowness of the death-rates from all causes and the low infant mortality-rates which were the rule. Owing to the comparative absence of influenza the death-rates from the respiratory diseases were considerably lower than in 1922. The reports generally showed that the introduction of the Milk Designations Order had stirred up considerable interest in the milk problem. In many districts there were clean milk competitions which secured the coöperation of dairy farmers in the production of a clean milk-supply. The reports from the districts where the milk clauses are in operation do not, however, indicate any lessening in the proportion of tuberculous milk. Prof. J. B. Buxton, F.R.C.V.S., dealt with this matter in an interesting paper read before the Farmers' Club on Dec. 8th, 1924. He showed that there was no reason to suppose that the prevalence of bovine tuberculosis or the frequency of tuberculous udders had in any way lessened in recent years, and he made out a strong case for the reintroduction of the Tuberculosis Order of 1914 or some amendment thereof. In the discussion which followed Prof. Buxton's contentions were not gainsaid.

The particulars which medical officers are asked to supply for 1924 are, in general, similar to those asked for in previous years. One of these is the number of women dying from the effects of childbirth. Study of the 1923 reports suggests the continued need for more uniformity in the classification of these deaths. At the present time England compares unfavourably in this respect with Scotland and many continental countries. The Scottish Departmental Committee made a recommendation that representation be made to the International Committee concerned with the classification of causes of death with a view to securing uniformity of method as well as of nomenclature in compiling official statistics of puerperal deaths. In addition to the variation of method as between one country and another, there is no uniformity when comparison is made between the various districts in England and Wales. For example, the figures given by the Registrar-General differ considerably from those given by the medical officers for the same districts concerned. No doubt the method of classification accounts for the difference. It is natural for the local medical officer to wish his district to appear in a favourable light as regards maternal mortality, but the Registrar-General is rather in the position of an impartial umpire whose decision is final.

Full particulars of the effect on vision resulting from ophthalmia neonatorum are asked for by the Ministry; a perusal of past reports shows that such particulars are frequently not supplied in full with the result that the extent of the damage done by this disease year by year remains unrevealed. The reports for 1923 did not indicate any progress in housing matters, rather the reverse.

OPHTHALMIC BENEFIT FOR MEMBERS OF APPROVED SOCIETIES.

ONE of the subjects before the Royal Commission on National Health Insurance now sitting is the best way to dispose of the surpluses which some of the approved societies possess and which are available for the granting of certain additional benefits to their members. There are 18 of these "additional benefits," and according to an official statement prepared for the use of the Commission and already published as a Blue-book¹ the most popular of the additional benefits, next to dental treatment, is the so-called "optical benefit." For the year 1924 nearly £40,000 is available for it. In one very large society, already, the claims have numbered 500 a week. A "model schedule" provides that "payment in respect of the cost of an optical appliance shall only be made on the production of a prescription from a qualified practitioner or a hospital." In some instances, says the statement, and in particular in rural districts, it has been found that to insist on this condition is impracticable and its strict enforcement has been relaxed. If we may believe a writer in the *Optician*, as a matter of fact, all the largest approved societies (and many of the smaller ones) send their members to an optician, and not to a qualified practitioner or a hospital. Whether or not this statement of the case requires qualification, there is, at any rate, sufficient truth in it to demand the attention of those medical bodies whose duty it is to have regard both to the professional interests of their members and to the preservation of the nation's eyesight. Three such bodies exist and are at present jointly concerned in considering the various problems under review with the object of ensuring that the model schedule of the Ministry of Health, just quoted, which at present, unfortunately, is in danger of becoming a dead-letter, may become really effective. The first of these three bodies is the Council of British Ophthalmologists, formed in 1918, representative of the Ophthalmological Society and the Ophthalmological Section of the Royal Society of Medicine; the second is the Ophthalmic Committee of the British Medical Association, and the third is the "Ophthalmic Benefit Committee," which has been formed during the past year, membership of which is open to those who hold or have held posts as surgeons, assistant surgeons, clinical, or refraction assistants at the ophthalmic hospitals or general hospitals with ophthalmic departments, and are in regular ophthalmic practice. The chairman of this Committee is Mr. H. L. Eason, senior ophthalmic surgeon to Guy's Hospital. It is understood that the aims of these three bodies with regard to the matter at issue are in perfect harmony.

Last spring a joint committee was formed by the first two bodies, which drafted a scheme for ophthalmic benefit, and this committee has now agreed to allow equal representation to the Ophthalmic Benefit Committee in any approach to the Ministry of Health and in considering the various problems under review. It is proposed that a list of ophthalmic medical practitioners qualified and willing to see insured members of approved societies should be prepared in accordance with the following principles. Anyone desiring to join in the scheme will have to furnish evidence (a) that he has held hospital or other appointments affording special opportunities for acquiring special skill and experience of the kind required for the performance of the service rendered, and has had actual recent practice in performing the service rendered or services of a similar character; or (b) that he has had special academic or post-graduate study of a subject which comprises the service rendered, and has had actual recent practice as aforesaid; or (c) that he is generally recognised by other practitioners in the area as having special proficiency and experience in a subject which comprises the service rendered.

¹ Appendix to Minutes of Evidence, Part I. Statements prepared by certain Government Departments. H.M. Stationery Office. 8s. 6d.

We understand that in the opinion of the three bodies there will be no difficulty in providing a satisfactory ophthalmic service on these lines. At one time it was thought that this could only be done in London and in the larger towns, but with the development of school clinics and duties in connexion with the Ministry of Pensions, ophthalmic surgeons are arranging not only to have their consulting-rooms at these larger centres where they are usually engaged in some capacity in the ophthalmic departments of the hospitals, but they visit, periodically, minor centres, and as soon as the demand is apparent there is little doubt that the supply will be equal to it. This is the first essential. The second is of at least equal importance—that the standard of work should be maintained at a high level. At a recent meeting of the Ophthalmic Benefit Committee, three members representing the North of England Ophthalmological Society were elected on to the executive, the conditions on which they agreed to serve meeting with general approval. They were as follows: (1) That there should be no lowering of the standard of work of ophthalmic surgeons, but that, on the contrary, it should be rendered more highly efficient; (2) that there should be an adequate fee for those taking part in the service; and (3) that their society should be responsible for the organising of the work in their area. A note in the supplement to the *British Medical Journal* for Dec. 13th states that the Medical Secretary would be glad to receive the names of medical men habitually doing ophthalmic work and complying with the conditions already mentioned, whose names are not already in the list, and who are willing to do the work. This list, the note states, can be supplied to the approved societies on application. An agreed fee of one guinea for each completed case of refraction has been mentioned, and it is believed that this would prove generally acceptable. At present the most urgent necessity is to demonstrate to the Ministry of Health that there are enough men and women in the medical profession competent and willing to do this work. To this end further names should be sent without delay, either to the Medical Secretary of the British Medical Association or to the Secretary of the Ophthalmic Benefit Committee at 30, Finsbury-square, London, E.C.

GOVERNMENT COMMITMENTS IN PUBLIC HEALTH.

DURING the last three days of the short December session a number of questions were put to Ministers which covered a wide range of public health matters. The replies are here briefly set out.

Housing.—Mr. Neville Chamberlain admitted that figures were not available to show how many houses there were still inhabited which had been condemned, and which had not been closed because the occupants were unable to find other accommodation. He added: "According to the reports of medical officers for 1922-23, representations were made during the year with a view to closing orders in respect of 3155 houses. Orders were made in respect of 2331 houses, and in 640 cases orders were determined after works of repair had been carried out. In the same period repairs were secured in the case of 542,834 houses as a result of the intervention of local authorities."

Asked if the Government would offer assistance and encouragement to builders of blocks of hygienic self-contained flats of a low rental value, and thus meet the needs of a district like Hackney where the only available spaces of building were those to be obtained by the clearance of slums, Sir Kingsley Wood (replying for the Minister of Health) said: "Assistance is available, both by way of loans and subsidy, under the existing Acts of 1923 and 1924, for the building of self-contained flats, and my right hon. friend will be glad to consider any such proposals submitted to him by local authorities, whether as part of schemes for the clearance of insanitary areas or

otherwise. Blocks of flats have already been erected, or are proposed to be erected, with Government assistance, in London and elsewhere."

Tuberculosis.—The Minister of Health, questioned as to the necessity of the further extension of the scheme of village settlements in the neighbourhood of large cities and towns for tuberculous persons and their families, replied (through Sir Kingsley Wood): "The provision of additional accommodation at the existing village settlements for tuberculous persons and their families is already in progress. The Minister does not propose to consider further extensions until more experience is available as to the value of this particular method of dealing with the problem."

Silicosis.—The Home Secretary, asked to state the number of deaths which had taken place in Sheffield among cutlery and other grinders during the last ten years, replied: "According to figures supplied by the medical officer of health for Sheffield, the total number of deaths among cutlery and other metal grinders in Sheffield during the ten years 1914 to 1923 was 1136, of which 524 were due to pulmonary tuberculosis, silicosis, or other fibroid disease. These figures give two deaths as due to silicosis unaccompanied by tuberculosis, but do not distinguish between cases of tuberculosis combined with silicosis and cases of tuberculosis unaccompanied by silicosis. The average age at death varies between 45.9 in 1918 and 52.9 in 1920."

Maternal Mortality in Childbirth.—Lieut.-Colonel Fremantle asked the Minister of Health if he would state what further steps he proposed to take with a view to reducing the exceptional maternal mortality in rural and in textile and coal-mining areas respectively; and whether, in the event of its not being regarded as the duty of the medical officer of health to investigate all maternal deaths due to childbirth and all cases of puerperal fever, whether fatal or not, he would take steps to make good these omissions.—Sir Kingsley Wood referred Colonel Fremantle to the circular on the subject of maternal mortality, which was issued by the Minister of Health on June 30th last and continued: "Attention was drawn in the circular to the need for investigating all maternal deaths due to childbirth, and all cases of puerperal fever, and the local authorities were urged to take action with a view to reducing the risk involved in childbirth. It is proposed to await the results of the issue of this circular before considering further action."

In answer to a further question on the same subject Sir Kingsley Wood replied: "In 1923 there were 2892 deaths of women classed to pregnancy and child-bearing, or a ratio of 3.81 per 1000 births. The average annual numbers of deaths so classed in the years 1891-95 (the nearest available figure to that asked for in the question) represented a rate of 5.49 per 1000 births. The figure is, however, based upon the more restricted classification then in use; and the comparable deaths for 1923 represent a rate of 3.6, showing a decrease of mortality during the period in question by 34 per cent. During the same period the death-rate from all causes of females aged 15 to 45 years has declined by 45 per cent."

Diphtheria Prophylaxis.—Mr. Broad asked the Minister of Health whether he was aware that in the town of Dallas, Texas, in the year 1919, 10 children were killed and over 60 others injured by toxin-antitoxin, administered in connexion with the Schick test for diphtheria; whether a similar disaster which occurred in Vienna recently, when several infants were killed by an injection of toxin-antitoxin, had been brought to his notice; and whether, in view of the possibility of serious injury, and even death, resulting from the use of toxin-antitoxin, he would discontinue the issue of circulars by his department in favour of the extension of the Schick system to workhouse children.—Mr. Neville Chamberlain replied: The answer to the first two questions is in the affirmative. As regards the third, I am advised that these regrettable

occurrences appear to have been due to unskilled technique or the use of unstandardised matter. The necessity of great care in these respects is emphasised on p. 54 of the Report of the Chief Medical Officer of the Ministry of Health for 1923. In all the circumstances I do not think it necessary to take any action as to the memorandum (68/Med.) issued on this subject by the Ministry in 1922, which the hon. Member will see is not confined to Poor-law institutions but has general reference to residential schools and institutions.

HOSPITAL NOTES.

ARTIFICIAL SUNLIGHT FOR LEEDS.—Leeds General Infirmary, which claims to possess the largest X ray department in the kingdom, still lacks the means of giving "artificial sunlight" treatment, and the need is emphasised by the recent acquisition of a first-rate apparatus by its neighbour, Harrogate, and by the fact that other institutions in the city are already provided. The infirmary is too heavily in debt to be able to incur the cost—estimated at not less than £1000—to make a modest beginning, and a movement is on foot in Leeds to provide the money.

THE NEW BETHLEM HOSPITAL.—It has now been definitely decided to remove Bethlem Hospital from the Lambeth-road, where it was established in the year of Waterloo, to a site at Shirley, near Croydon. An estate of 340 acres has been purchased with amenities which, says Alderman Sir Charles Wakefield, the President, can be "conserved for all time." Deputations of officials and governors are to visit the leading mental hospitals in England and other countries, and perhaps America, to familiarise themselves with modern curative methods which it is impossible to adopt with any fullness in the present unsuitable buildings and still more unsuitable surroundings.

GOVERNMENT HELP FOR VOLUNTARY HOSPITALS.—Speaking at a Mansion House meeting of the Metropolitan Hospital Sunday Fund, Mr. Neville Chamberlain, the Minister of Health, emphasised the importance of maintaining the voluntary system, and added that he hoped, if he remained sufficiently long in his present office, to "do something to put the matter on some satisfactory and permanent footing." The £39,724 collected on Hospital Sunday is a decrease of £3443 on the previous year, a falling-off which Mr. Holland-Martin, the Chairman of the Finance Committee, attributed in part to the growth of the "week-end" habit.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED DEC. 20TH, 1924.

Notifications.—The following cases of infectious disease were notified during the week—namely, small-pox, 76; scarlet fever, 1673; diphtheria, 740; enteric fever, 53; pneumonia, 1006; puerperal fever, 38; cerebro-spinal fever, 5; acute poliomyelitis, 10; acute polio-encephalitis, 2; encephalitis lethargica, 41; dysentery, 13; ophthalmia neonatorum, 83. There were no cases of cholera, plague, or typhus fever notified during the week. Of the 13 cases of dysentery, 2 were reported from Bristol, 1 from St. Albans R.D., 3 from Friern Barnet (Mx.), 3 from Woking, 3 from Reigate R.D., and 1 from Greetland (Yorks, W.R.).

Deaths.—In the aggregate of great towns, including London, there were 2 deaths from enteric fever, none from small-pox, 13 from scarlet fever, 33 from diphtheria, 84 from measles, and 82 from influenza. In London itself the deaths from diphtheria numbered 9 and from infantile diarrhoea 14.

ROYAL SOCIETY OF MEDICINE.—The next social evening of this society will be held at 1, Wimpole-street, London, W., on Monday, Jan. 19th, at 8.30 P.M., when the President, Sir St. Clair Thomson, will receive the guests, and at 9.30 P.M. Miss Lena Ashwell will give an address on the Drama as a Necessity of Civilised Life.

Correspondence.

"Audi alteram partem."

INTUBATION OF THE COMMON BILE-DUCT.

To the Editor of THE LANCET.

SIR,—The case of intubation of the common bile-duct for stricture recorded by Mr. Zachary Cope in THE LANCET of Dec. 6th, 1924, and the comment thereon by Sir Hugh Rigby are of great interest. Examples of stricture of the common duct are, unhappily, not rare. They are due to maladroitness of performance of the operation of cholecystectomy. Portions of the common duct, or of the common hepatic duct, may be removed; or the cystic duct may be divided so close to the common duct as to cause an inflammatory thickening around the ligature, to be followed in a few months by stenosis. I have operated on several such cases by various methods, and I have left a tube in the common duct on four occasions. There need be no anxiety, I think, as to the permanent retention of the tube within the duct if a little device adopted by me is followed. A special tube should be inserted. I have had some tubing made for this purpose, with a thicker wall and smaller lumen than is usual, and of a diameter equal to a No. 4 catheter. The tube is fixed into the duct by a single stitch of finest catgut (8 or 9 nought), and about 3 inches of it, guided, if necessary, by a stylet, are passed through the ampulla into the duodenum. The "Jutte tube" serves this purpose well. The constant passage of food through the duodenum and the contractions of the gut pull upon the tube lying free within it. By degrees the tube is loosened and the whole length of it escapes into the intestine. I have known the tube to be discharged by the rectum as late as eight weeks after its insertion, and as early as three weeks. In no case has it been permanently retained. Too long a retention would no doubt lead to incrustation of the tube, and to disasters consequent upon this condition.

I am, Sir, yours faithfully,

Leeds, Dec. 24th, 1924.

BERKELEY MOYNIHAN.

REX v. BATEMAN.

To the Editor of THE LANCET.

SIR,—As I have had several letters addressed to me on the above case, may I be pardoned for addressing you in the matter? It would appear to me that there has been an unfortunate miscarriage of justice in a case admittedly difficult for laymen to view in a proper perspective.

The prosecution sought to prove:—

(a) That gross negligence amounting to criminal negligence must have occurred in removing a uterus together with the placenta after confinement, and, if this were not proved to the satisfaction of the jury, that

(b) It was criminally negligent not to have removed the patient for operation after such an accident had occurred.

The prosecution further inferred that in not removing the patient, the doctor was actuated by the hope that she would shortly die when a certificate would be given and nothing more heard of the matter. This insinuation was indignantly denied by the defendant.

With regard to the two specific points (a) and (b), as a witness for the defence, I should like to put the point of view held by a practising obstetrician to the profession at large.

(a) It was admitted that the presentation in this case was a complicated one, either a transverse, or a complex one of head, foot, and cord. It was my opinion that a rupture of the uterus must have occurred during the version which was done to effect

delivery. It is well known that a rupture of the uterus may attain very wide dimensions quite out of proportion to the force used in producing such a rupture. The wider such rupture be, the less force would be required for a doctor, mistaking the edge of the rent for the edge of the placenta, to remove the uterus together with the placenta instead of the placenta alone.

(b) When such an accident has occurred it will be obvious to anyone with any surgical experience that to move a patient down four flights of stairs (such was the position in this case) to a hospital would have been to ensure her death in transit. It is very strongly my view that absolute rest was the only chance of recovery such a patient would have, and that in enjoining that rest the doctor in charge could not fairly be said to have accelerated the patient's death. Whether there was a more appropriate time for removal between the date of confinement and the actual time at which this particular patient was removed no one can say except the medical man in charge. The evidence of the family "that she seemed brighter" was put to the jury in this connexion—surely not a fair direction.

In addition I would state that the above medical evidence of obstetricians was not put to the jury at all, the only medical evidence submitted to them being that of a pathologist.

I am, Sir, yours faithfully,

London, W.

J. BRIGHT BANISTER.

To the Editor of THE LANCET.

SIR,—In some respects Dr. Bateman was particularly unfortunate. The charge of negligence crystallised itself at the trial into two main forms, as the judge's direction to the jury indicates. The two heads may have been regarded either as alternative or as cumulative. In view of the characteristically fair admissions of the professional witnesses for the Crown, it seems unlikely that the accused can have been convicted upon both heads. The collective mind of a jury is an inscrutable instrument. Under which head did it give its verdict? Or was there a sort of compromise due to a half-persuasion on each of the two heads? It is a pity that the jury was not asked (as would probably have been done in a civil action for negligence) to make specific replies to specific allegations of negligence.

It is even more unfortunate that the summing-up contained no express warning that Dr. Bateman was not being tried for anything that he said (or did not say) after his treatment of the poor woman who died. His failure was that he gave way to a natural impulse to conceal a tragedy which was irremediable. This was, perhaps, the one feature which the jury could grasp unaided in a case full of complex surgical technicalities. Was there not a danger that the jury, if inclined to find Dr. Bateman at fault here, might forget that he was not charged with loss of nerve but with malpraxis?

I am, Sir, yours faithfully,

Dec. 28th, 1924.

A BARRISTER.

* * We publish elsewhere a full report of the summing-up of Mr. Justice Shearman in this case, which, it will be seen, follows the line fairly indicated by Dr. Bright Banister. The clinical side of this tragic case was not dwelt upon or explained to the jury. The jury never seem to have been informed of the strong medical support, that would have been forthcoming from obstetricians, to the view that immediate removal to the hospital for immediate operation might have meant immediate death; nor does it seem to have been explained to them that the size of a rent in the uterus is not dependent upon either the amount of force used or the extent of any miscalculation.—ED. L.

CONJUGAL TUBERCULOSIS.

To the Editor of THE LANCET.

SIR,—In your issue of Dec. 13th Dr. S. Rowland courteously criticises some of the views expressed by me (THE LANCET, 1919, ii., 606). With several of his observations I entirely agree. No doubt the personal factor comes largely into consideration when one observer is deciding whether a patient should be considered tuberculous, and the almost mathematical accuracy provided by positive sputum results, death certificates, and autopsies, is far the most desirable statistical basis. But it is to be doubted whether such accuracy is to be obtained in a problem so intricate and many sided, and the attempt may lead us seriously astray. Nor is careful experimental work, which shatters so many scientific illusions, possible in this instance. If we had a few more St. Andrews Institutes (to my mind the greatest clinical advance of the century) they could solve the problem for us in three generations and might well prove that my views are mistaken; but for the present we have only opinion and statistics to lean upon, and I cannot yet see sufficient evidence to disprove my views.

1. As pointed out in my paper, not every consort was examined, and there is no doubt that those most willing to submit to examination were those who already suspected illness; nevertheless, more accurate work is possible when contacts are examined in the home, as they are in Devon, than when they have to attend a dispensary for the purpose.

2. To found conclusions on positive and negative sputum results may be misleading unless some definite standard of negativity is adopted. The question is very difficult unless the patient is under direct hospital observation. To give a patient a sputum outfit for him to send off, and on the result to write him down as negative, is most unsatisfactory—yet how often this is done. I have obtained a positive result at the twentieth examination, after six years' observation, in a patient whose main disability was, and still is, bronchitis and emphysema.

3. A positive sputum after infection announces the danger of death from tuberculosis and implies that we are dealing with a patient of low resistance; still more is this the case if deaths alone are counted. The majority of the consorts of tuberculous persons have higher resistance than their mate; moreover, it has often seemed to me that their resistance is increased by the repeated small doses they receive before the massive infection which occurs in the terminal phases of the illness.

4. How often one sees the spouse of a tuberculous patient wilting and coughing, with physical signs in the chest and yet no sputum, or a negative sputum. Most of these cases clear up quickly when given a chance, but if we are for this reason to regard them uninfected, it distorts our statistics and leads to wrong conclusions.

5. Personal resistance varies very greatly; we constantly see examples of this in different members of a household equally exposed to infection. The great majority of people fortunately possess a high resistance, and the tuberculous person is generally married to one of the great majority. It is only when by coincidence a member of the low resistance minority is married to another, similarly handicapped, that conditions are provided that may lead to inclusion in a positive sputum or death series.

6. Dr. Rowland rightly states that I attach more importance to the seed than to the soil, but I by no means deny the importance of the soil, or of such serious factors as worry and subnutrition. It is the soil factor, indeed, which prevents the marriage of tuberculous persons universally ending in disaster for the mate. For the children of working-class patients the position is disastrous enough, for my figures lead me to believe (THE LANCET, 1923, i., 11) that these children are seven times more likely to contract the disease than those of healthy parents.

7. I do not in any sense disbelieve in a widespread tuberculous infection in childhood, and would attribute 50 per cent. of adult cases to reactivation of this focus as the result of accident or adverse circumstances; but the childhood infection does not confer a prolonged immunity, and I regard the other 50 per cent. of adult cases as due to a reinfection. An experimental infection does not confer prolonged immunity in animals, and it seems more likely that the immunity of adults exposed to massive infection is due either to a congenital high resistance, or a smouldering infection of their own, which is indeed far from uncommon.

I am, Sir, yours faithfully,

Paignton, Dec. 15th, 1924.

E. WARD.

SUCTION IN SURGERY.

To the Editor of THE LANCET.

SIR,—I have been much interested in the correspondence which has followed Mr. N. C. Lake's article on this subject in your issue of Dec. 6th, 1924. For some years I have been using suction in my own department of aural surgery and in routine otological work in place of syringing, which is still too much in daily use and should long ago have been discarded in favour of suction.

It is remarkable to learn how largely suction has taken the place of syringing and mopping up in general surgery, especially in clinics and operating theatres in America, and particularly in the region of the abdomen. If there is one region in the body above all others in which suction is eminently applicable as a method of preparing the field of operation and clearing away blood, pus, and debris during operation it is that of the ear and its annexes. The intricate anatomical arrangements in the middle-ear and its accessory recesses are, indeed, favourable for rapid and extensive progress of bacterial activity. To syringe forcibly a discharging ear may have the effect of driving purulent outflow into deeply-seated and dangerous positions, such as the attic, aditus, mastoid antrum, and mastoid cells, and may even precipitate such an almost invariably fatal complication as septic meningitis. It is striking to know how many years ago syringing out the abdomen during operation was gradually dropped—in my student days it was the usual custom—in favour of mopping-out. It was considered correct to flush the abdominal cavity with gallons of warm fluid.

I think it was the study of this change from syringing to sponging in abdominal work that first induced me to reflect on the disastrous results that often followed forcible aural syringing in the presence of septic discharge. Now, again, the abdominal surgeons are once more in the van in abolishing mopping and syringing out and substituting suction. It will be well for aural surgery when a similar change-over becomes universally recognised and adopted. I have found in my own work in aural and nasal surgery that a thorough clearing of the region about to be operated upon by preparatory suction, and so securing a clear field for operation, is the best way to get a good result and avoid serious complications such as septic meningitis.

Suction is always safe and effective. The suction of all discharging ears is what I advocate and am anxious to see carried out by practitioners and nurses in all hospitals and children's clinics. From a large experience of its use in the case of patients of all ages, in both acute and chronic discharge, I have no hesitation in stating that at least 90 per cent. of all patients would recover with dry, hearing ears, and the necessity for any operation would be avoided, if syringing were abolished and suction substituted. My experience justifies me in maintaining that no septic ear—whether acute or chronic—should ever be operated upon until suction has had a fair trial—in acute cases for 48 hours, and in chronic cases for at least a month. The only exception to this statement

would be where an acute case had been seen too late and an abscess had already formed in the mastoid region, in which case an operation would, of course, be imperative.

The easiest and simplest way to apply suction to the aural cavity is by attaching a short piece of rubber tubing to the nozzle of a medium-sized glass or larger metal syringe, inserting this into the ear and then drawing out the piston, when the purulent secretion is all sucked away. This can be done repeatedly until the ear is dry: it is just the opposite action to syringing with the precautionary addition of the rubber tubing. It is an advantage if this is done with the aid of a good bright reflected light. The more elaborate method, and, of course, more effective, is to use a motor suction pump with specially made fine pointed glass tubes, which, being bent in various directions, can under a good reflected light be inserted into the various recesses of the tympanic cavity up into the attic, back into the aditus, and down into the depressed floor of the tympanic recess.

These suction tubes, of various shapes and sizes, I have had made for me by Messrs. Allen and Hanburys, Wigmore-street.

I am, Sir, yours faithfully,

WM. STUART-LOW.

Wimpole-street, W., Dec. 22nd, 1924.

CANCER STATISTICS AND STATISTICIANS.

To the Editor of THE LANCET.

SIR,—In your leading article of Dec. 27th on this subject you point out the paucity of accurate data on the incidence of malignant tumours in the areas Mr. F. L. Hoffman classes as "uncivilised," including India, with probably the oldest civilisation in the world. This deficiency I have attempted to remedy in the Finlayson lectures of the Faculty of Physicians and Surgeons delivered in Glasgow last month, which will appear in due course in the *Glasgow Medical Journal*, including an analysis of 1190 tumours I cut sections of at the Calcutta Medical College Hospital and 1000 from the records of St. Mary's Hospital, London, which revealed a slightly higher percentage of malignant tumours, including sarcomata, in the tropical area, instead of eight times as many in this "civilised" country, which Mr. Hoffman assumes in support of his theory of cancer causation.

I am, Sir, yours faithfully,

London, Dec. 28th, 1924.

LEONARD ROGERS.

THE CLINICAL SIGNIFICANCE OF CONSTIPATION.

To the Editor of THE LANCET.

SIR,—In his letter in THE LANCET of Dec. 20th (p. 1310) Dr. Reginald Miller draws attention to the importance of abnormal permeability of the intestinal (colonic) mucosa as the essential factor in the production of intestinal toxæmia. He allows, of course, that abnormal toxicity of the intestinal contents—owing to constipation or other causes—is also an important factor. It is an old observation that in extreme constipation there need be no great excess of indican and similar bodies in the urine, whereas there is very great excess whenever inflammatory diarrhoea occurs. Chronic constipation may exist for many years in persons whose diet is relatively plain and who avoid excess, without causing obvious signs of intestinal toxæmia, but when, at length, owing to infection or habitual use of purgatives or chronic irritation produced by the constipation, the colon becomes damaged, then signs of intestinal toxæmia begin to appear. It is at the latter stage that in certain persons a feeling of fatigue, distress, or somnolence may be noted after the bowels act. Such symptoms are apparently of toxic origin and tend to occur in rather

feeble individuals who for years have been accustomed to open their bowels every other day with purgatives. Following the fluid action of the bowels the damaged mucous membrane permits abnormal absorption of toxic material, doubtless especially from the fluid material left in the rectum. Such persons usually feel at their best on the days between those on which the purgatives act. I referred to this point in a discussion, *Medico-Chirurgical Transactions*, London, 1907, Vol. XC., pp. 615-616.

I am, Sir, yours faithfully,

F. PARKES WEBER.

Harley-street, W., Dec. 20th, 1924.

PNEUMOCOCCUS MENINGITIS.

To the Editor of THE LANCET.

SIR,—At a combined section meeting of the Royal Society of Medicine, reported in your issue of Dec. 20th, 1924 (p. 1281), the opinion was expressed by Dr. J. G. Greenfield, and shared by Dr. D. Nabarro, that pneumococcal meningitis always kills. It may therefore be of interest if I give an outline of a case which fought a winning fight. My notes were made daily at the time.

In Washington, D.C., on Oct. 29th, 1921, I was called at 8.30 A.M. to see a lad of 16. During the night he had arisen, vomited, and gone back to bed, and at the hour named was found wildly delirious. Lumbar puncture was done at 9.30 A.M.

Dr. Clarence Rice, of Garfield Hospital, gave the following report on the fluid: "Markedly turbid. Protein: marked increase. Cells per c.mm. 16,000. Polymorphs, 92 per cent.; mononuclears, 8 per cent. Smears: many leucocytes, few lymphocytes, and a few Gram-positive, lancet-shaped, encapsulated diplococci having the morphological appearance of pneumococci. Culture: pure culture of pneumococci."

I called Dr. William Hough into consultation and asked him to assume control of the treatment. The same evening Dr. Hough drew off the spinal fluid. Next day this was repeated and again every day up to Nov. 7th, with the exception of Nov. 2nd. The fluid on the 7th was clear, contained eight cells per c.mm. and on culture was sterile. No further puncture was made. On Nov. 18th patient was out of bed for the first time. On the 22nd a note was made, "Somewhat slow in convalescing." He was eating well. There was ptosis of the left eyelid. On Dec. 5th, headache and vomiting; on the 7th, giddiness; on the 8th, much frontal headache with tenderness on percussion above right eyebrow. Blood leucocytes, which were 9100 on Dec. 7th, were now 14,200. On Dec. 9th Dr. Hough was again called. On the 11th Dr. Harry Kerr was also summoned, and it was agreed that there was cerebral abscess. On the 12th Dr. Kerr opened the skull at the spot tender on percussion, and at a depth of 4 cm. found pus. He drained with rubber tubing. Convalescence was anxious, but a fine recovery took place with unimpaired mentality.

An intranasal operation had been done 12 months before the illness, and since then life had been a burden to the lad on account of constant drip of presumably cerebro-spinal fluid. To the patient's great joy there was after the illness no return of the nasal flux.

I am, Sir, yours faithfully,

JAMES CAMPBELL, M.B., Ch.B.

Lerwick, Shetland, Dec. 24th, 1924.

THE ROYAL COMMISSION ON NATIONAL INSURANCE: AN APPEAL.

To the Editor of THE LANCET.

SIR,—It seems certain that the evidence to be tendered by the British Medical Association will assume the principle of the National Insurance Act to be sound, and ignoring the more subtle moral and social effects, will concentrate on benefits, even advise extension. It is clear that extension points in the direction of State Socialism. Of course, the Association cannot plead opposing views officially—i.e., it is pledged by a group to the support of a political theory.

It is fatally easy to feel that all is well with the world if all is well with oneself. There is no doubt that many panel doctors are the richer for the Act; nor do they realise that from the Exchequer point of view that is an a priori objection. That section of us is organised. The objectors are not organised, but scattered, and whether from esprit de corps or the feeling that it is ungenerous to point to the fact that they are being taxed for the panel doctor, they never act, scarcely ever speak. But it is past that now; here is a chance of helping a nation forward, and no man should shirk the question. Two recent instances have shown how dangerous a course we are on: (1) the order to make a doctor responsible for the default of a parent to notify a birth within a given time, and (2) the savage fine of £1000 on a doctor; in both cases by, not a judicial or a legislative but an executive body. Unless there is a change no man henceforward is safe from the bureaucracy.

The Act takes illness as the norm and promotes health by provision of medical benefit. But all history shows that national health depends on the standard of living, especially of the poorer classes. The effect of the Act on the standard could clearly be seen up to the war, and the result was the largest increase in phthisical mortality in our records. The war had an almost unique effect on that standard; it raised it among the poor. The mortality began a huge decline during the war. Similar effects have been noticed in the U.S.A.; its appalling mortality has suffered a record decline. Now it is a contradiction in terms to raise that standard of living by a tax on production. Such a tax bears hard on the small employer, hurts not at all the large employer when once he has readjusted prices, bears cruelly on the working man with a family, is trivial to the young unmarried, unless it cause unemployment. It is unjust where it strikes, it is futile when it aims at the strong.

I repeat it is a grave national question, and I appeal to those men who have stood aloof, feeling it is no concern of theirs, especially to the consultants. Every doctor knows, perhaps has deplored, how the Labour Party is obsessed by the notion that the State is a bottomless well, from which every need can be supplied. For humanity's sake, and England's, do not by inertia encourage that pathetic and dangerous fallacy. The Commission has consented to receive evidence on the principle. To make that evidence effective, it is desirable to have the support of a considerable body of doctors. Will any sympathiser send me a postcard with his or her name, and any medical friend's (not pledging themselves to any particular doctrine), to say that he, she, or they deprecate any extension of the Act until the basic principle has been thoroughly reconsidered?

I am, Sir, yours faithfully,

B. G. M. BASKETT.

29, Daniel-street, Bath, Somerset, Dec. 27th, 1924.

ENCEPHALITIS AND PLEOMORPHISM.

To the Editor of THE LANCET.

SIR,—Dr. F. G. Crookshank has commented favourably in your columns (see THE LANCET, 1924, vol. ii., p. 1311) on a recent communication of mine to the *British Medical Journal*.

He points out that Dr. Regan's case of atelectasis in poliomyelitis is a particular instance of a type of visceral paralysis which not infrequently occurs in this and allied diseases—for example, in encephalitis and in influenza with nervous symptoms. For is it not probably a fact that poliomyelitis and encephalitis are less distinct in nature than their names would suggest—that they tend, in fact, to run into one another, as also into the influenzas presenting cerebral and spinal complications, and so eventually into ordinary influenzas? Dr. Crookshank has provided us with an excellent example of that synthetic manner of thinking which medicine so badly needs after

several generations of analysis and pigeon-holing *à outrance*. And it is surely a hopeful sign that we have in the last three numbers of THE LANCET at least two other contributions in which this more comprehensive method of approaching medical facts is strongly evidenced. I refer to the "note" on alastrim and variola by Prof. Ricardo Jorge of Lisbon (pp. 1317 and 1366) and to the letter of Dr. James Young of Edinburgh on bacterial pleomorphism (p. 1207). Just as Dr. Crookshank presents encephalitis and poliomyelitis as offshoots from the common stock of influenza, so Prof. Jorge presents alastrim, varicella, cow-pox, and the "mild small-pox" of Gloucester as allied members of the varioloid family—different certainly, but no less certainly related. May it not be that *under certain conditions of time and place*, the different members of a group may run into one another—that one may in fact (i.e., clinically and for practical purposes) actually *become* another? Although such a conception undoubtedly militates against the dominant teaching—viz., that "exact diagnosis" (with its consequent opportunity for scheduling) should be the doctor's main concern, I am strongly inclined to believe that it is supported by a growing body of clinical experience.

Finally, the same principle which Drs. Crookshank and Jorge emphasise in the clinical and epidemiological field, Dr. Young illustrates from that of bacteriology, where he gives good reasons for believing that various of the best known forms of micro-organism may, as a result of various changes in the medium, develop from some kind of "bacterial plasm." I would press for a fuller recognition of pleomorphism in disease.

I am, Sir, yours faithfully,

Edinburgh, Dec. 28th, 1924.

A. J. BROCK.

PROF. JORGE AND CHRISTIAN SCIENCE.

To the Editor of THE LANCET.

SIR,—In an article by Prof. Ricardo Jorge (Lisbon), appearing in your issue of Dec. 20th, 1924, he makes a statement that Christian Scientists clamour for freedom from prophylaxis. The reverse of this is true, for Christian Scientists are taught in the Christian Science text-book, "Science and Health with Key to the Scriptures," by Mary Baker Eddy, p. 369, "The prophylactic and therapeutic (that is the preventive and curative) arts belong emphatically to Christian Science, as would be readily seen, if psychology, or the Science of Spirit, God, was understood." Christian Science teaches one how to gain the Mind of Christ, and to think as Jesus thought. This they find is the great preventive of disease as well as its curative method.

I am, Sir, yours faithfully,

CHARLES W. J. TENNANT.

Christian Science Committee on Publication,
Talbot House, Arundel-street, Strand, W.C.,
Dec. 20th, 1924.

A DISCLAIMER.

To the Editor of THE LANCET.

SIR,—As the result of five minutes' courtesy to a correspondent introduced to me by friends in London, I have been made the subject of a blatant and vulgar article in a London daily paper. The article is full of errors, exaggerations, and inaccuracies. It was published without my having seen it and in the face of a specific request that my name should not appear in any article that the correspondent wrote. I have retired here for health, peace, and quiet, and the imagination and pertinacity of such correspondents will do much to frustrate my objects. I shall be grateful to you if you will publish this disclaimer.

I am, Sir, yours faithfully,

W. H. CLAYTON-GREENE.

Guernsey, Dec. 20th, 1924.

Obituary.

PROFESSOR HEDINGER.

MEDICAL science in Switzerland has to record a great loss. On Christmas Eve died at Zurich, after a short illness, Dr. Ernst Hedinger, University professor of pathological anatomy and histology. Born in 1876 at Schaffhausen, and educated in Berne, Hedinger studied medicine at the Universities of Berne, Munich, and Berlin, graduating in Berne. He then became in succession clinical assistant under such great teachers and research workers as Kocher (surgery), Sahli (internal medicine), and Jadassohn (dermatology). Having thus gained a wide clinical knowledge and experience he went to his favoured branch, pathological anatomy, becoming assistant to Prof. Langhans at the Pathological Institute at Berne. He was only 30 years old when he was appointed professor of pathological anatomy at the University of Basle, a post which he held till 1922, when he returned to Berne to succeed his late master. Hedinger was an indefatigable worker, the author of numerous dissertations chiefly on morphological subjects. His diagnostic skill was highly appreciated by all his clinical colleagues. In 1914 he undertook a special mission to South Africa on the invitation of the Union Government to investigate trypanosomiasis in cattle. This journey brought him into contact with General Botha and other South African statesmen, an experience which gave him a sympathetic understanding of the British Commonwealth at the beginning of the great conflict. Soon after his appointment to Basle Hedinger joined the editorial staff of the *Correspondenz-Blatt für Schweizerärzte*, the leading Swiss medical paper, which under his guidance was transformed into the *Schweizerische medizinische Wochenschrift* of enlarged size and raised scientific standard. Whether by mouth or by pen Hedinger had a natural gift for lucid exposition, and the present generation of Swiss medical men owes its working knowledge of pathology largely to his teaching.

ANDREW ROBERT WARNER, M.D. OHIO,

EXECUTIVE SECRETARY, AMERICAN HOSPITAL ASSOCIATION.

ALTHOUGH Dr. A. R. Warner had been ill with heart disease for nearly a year, his sudden death recently at his home in Dearfield, Illinois, came as a great shock to his colleagues, since he was apparently on the road to recovery.

Dr. Warner was born in Pulaski, New York, in 1875. He graduated from Hamilton College in 1899 and from Western Reserve University Medical School, Cleveland, Ohio, in 1906. Subsequent to graduation he practised medicine in Cleveland for a few years. The first hospital position Dr. Warner held was that of assistant superintendent of Lakeside Hospital, Cleveland, and in 1913 he became its superintendent, a position he held until his appointment as executive secretary of the American Hospital Association in October, 1919. Dr. Warner was always deeply interested and active in the development of organised hospital activities. He was one of the founders of the Cleveland Hospital Council and of the Ohio Hospital Association and served as President of the Ohio Hospital Association in 1918 and 1919. He was also instrumental in developing and organising the American Conference on Hospital Service and served continuously as Vice-President of the Conference from the time of its organisation.

From the beginning of his hospital career he was actively interested in the work of the American Hospital Association, serving on several of its important committees. In 1918 he was elected its President. His earnestness and enthusiasm in the organisation of hospital activities won for him not only nation-wide, but international recognition.

BERTIE RONALD GORDON RUSSELL,
M.D. ABERD.

THE death of Dr. B. R. G. Russell on Dec. 22nd, 1924, at the early age of 44, after a short illness, is a grave loss to the serious investigation of cancer in this country. Russell was educated at the Grammar School and Marischal College, Aberdeen, and was one of the younger members of the school of pathology founded by the late Prof. Hamilton. After graduation he studied for a year under Marchand in Leipzig and returned to Aberdeen to take up the McRobert Fellowship for Cancer Research. While holding this appointment he joined the staff of the Imperial Cancer Research Fund as a voluntary worker in 1907, and in 1908 became a member of the ordinary staff of the Fund.

During the war he served in the Royal Army Medical Corps, at first at Woolwich and later at Malta. His health broke down in his second year at Malta, and

DR. GORDON RUSSELL.

he was invalided home out of the army. After a year at Southbourne Sanatorium he returned to work in London till the end. Russell's contributions to the experimental study of cancer were notable, and all characterised by thoroughness and technical competence. The histological analysis of the immunity to tumour transplantation, the development of sarcoma in the stroma of transplantable carcinoma, and the phenomena of concomitant resistance during progressive growth, he found in tangled confusion and left in order. These contributions all belong to the period before 1914. In the period after 1918 his researches fall into two categories. To the first belongs the work on the production of sarcoma by the subcutaneous inoculation of tar. The second comprises his studies on respiration and carbohydrate metabolism of isolated tissues, normal and cancerous. These researches led to a recognition of apparently specific differences in pentose metabolism, between normal and cancerous tissues of the mouse and rat. He was engaged on chemotherapeutic experiments based on these differences at the time of his death.

The thoroughness and objective clarity of all Russell's work were expressions of his critical and original mind, qualities which made him a touchstone in the laboratory, for men or work. The flawless courage with which he faced the situation following his breakdown in health, rigorously husbanding his energies for the one purpose of his investigations, will remain an enduring memory to those who worked with him.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdr. J. A. Thompson is placed on retd. list, with the rank of Surg. Capt.
Surg. Lts. G. B. Tarring to *Spenser*, on recommg.; R. Burns to *Malcolm*; C. Joiner to *Royal Sovereign*; and E. J. K. Weeks to *Eagle*.

ROYAL ARMY MEDICAL CORPS.

Capt. T. Young relinquishes the temp. rank of Maj. on ceasing to be empld. as a Dep. Asst. Dir. of Hygiene.
Capt. F. A. Roddy retires, receiving a gratuity, and is granted the rank of Lt.-Col.

ARMY RESERVE OF OFFICERS.

W. G. Hazelton, late Cadet, Belfast University Contgt., O.T.C., to be Lt.

MILITIA.

Maj. A. R. Dale relinquishes his commn. and retains the rank of Maj.

TERRITORIAL ARMY.

Maj. A. Walker resigns his commn. and retains the rank of Maj. with permission to wear the prescribed uniform.

Medical News.

SOCIETY OF APOTHECARIES OF LONDON.—At examinations held recently the following candidates passed in the undermentioned subjects:—

Surgery.—A. H. Allam, St. Mary's Hosp.; D. T. Jenkins, Edinburgh; A. Mishriky (Sect. I.), St. Mary's Hosp.; and J. Wilson, Leeds.
Medicine.—S. W. Cuff, St. Bart's Hosp.; D. T. Jenkins, Edinburgh; T. McD. Kellough and F. R. Ratnagar, Guy's Hosp.; C. C. Taffs, St. Thomas's Hosp.; and R. D. M. Tims, Cambridge and St. Thomas's Hosp.
Forensic Medicine.—C. L. Copeland, Univ. Coll. Hosp.; T. G. L. Davies, St. George's Hosp.; R. Norrie, St. Andrews; K. Samaan, Manchester; P. B. Skeels, Guy's Hosp.; W. T. Swanton, Cork and Charing Cross Hosp.; C. C. Taffs, St. Thomas's Hosp.; R. D. M. Tims, Cambridge and St. Thomas's Hosp.; and C. W. Warne, Guy's Hosp.
Midwifery.—W. T. Swanton, Cork and Charing Cross Hosp.
The Diploma of the Society was granted to the following candidates entitling them to practise medicine, surgery, and midwifery: K. Samaan, W. T. Swanton, and R. D. M. Tims.

UNIVERSITY OF MANCHESTER.—At examinations held recently the following candidates were successful in the subjects indicated:—

FINAL M.B. AND CH.B. EXAMINATION.

R. S. Adam, J. K. Barr, C. E. W. Bower, C. V. Brown, Stella H. Brown, Elsie Catlow, William Chadwick, S. F. Clegg, Jenny D. Craig, Mary S. Davies, T. E. Davies, Stanley Devine, Florence M. Duckworth, Charles Eccleston, J. D. Farquhar, Leo Fay, R. A. Ferguson, Anne H. Glancy, G. H. Hayle, A. H. Heyworth, J. N. Hudson, Elizabeth G. Humble, P. G. Johnson, A. M. MacGill, H. T. Simmons, A. B. Slack, Robert Slater, A. R. Somerford, Ronald Walshaw, S. E. Ward, Hugh Whittle, R. M. Williams, S. P. Wilson, Frank Yates, and J. M. Yoffey.
Forensic Medicine and Hygiene and Preventive Medicine.—Madge E. Edwards and Ethel Morris.
Forensic Medicine.—A. R. Adley-Redfern.
Hygiene and Preventive Medicine.—William Mottershead, Samuel Whalley, and P. B. Wood.
Obstetrics and Surgery.—C. H. Bamford, Solomon Bernstein, N. W. Bolton, Lilian Bond, G. H. H. Booth, Geoffrey Coope, John Crook, T. A. Danby, A. A. Davis, N. E. Delaney, Kathleen Dickinson, L. F. Evans, Mary Evans, Miriam Florentin, J. B. Fulton, E. A. Gerrard, E. St. G. Gilmore, Riad Girgis, Mary Harburn, May Johnson, Walter Johnson, J. T. C. Keddle, Barbara M. Knight, G. F. Langford, G. H. March, C. T. Marshall, E. A. Marson, S. L. Micklow, R. M. Pearce, Archer Pearson, Joan Robinson, M. P. Sagar, N. F. Seed, W. H. Shepley, Joseph Shlosberg, Agnes G. Smiley, F. H. Smirk (distinction in Obstetrics), Lois Stent, Jane B. Stubbs, Jacobus Viljoen, J. C. Wilson, Reginald Wood, and N. A. J. Young.
Obstetrics.—Frances H. Bowden, T. K. Clifford, S. J. Firth, I. H. Freedlander, T. S. Hanlin, E. P. Johnson, W. D. Mitton, Francis Reynolds, B. R. Sandiford, A. D. Shubsachs, and W. S. Slater.

THIRD M.B. AND CH.B. EXAMINATION.

Pathology.—J. K. Anderson, Frank Appleton, R. H. Barnes, Helen G. M. Bennett, Solomon Bernstein, George Bridge, Gladys Brocklehurst, R. S. Davidson, Margaret Dyson, Ernest Firth, Alec Fleming, C. F. Garfit, J. S. Goller, Basil Haring, Fanny Howe, George Metcalfe, C. T. Mills, Joseph Parness, Richard Pendlebury, Marjorie Reekie, Leonard

Rosenthal, Kathleen Sheehan (with distinction), Maurice Sheehan, Florence V. Stephen, R. H. Tootill, Vera Urnson, G. R. Walker, and Florence Whitrow.
Pharmacology.—Doris Bernard, Solomon Bernstein, Frank Cort, H. V. Crabtree, Margaret Egan, Arthur Hancock, Ernest Heard, H. H. Jackson, Nora Ridchalgh, and Herbert Townley.

UNIVERSITY OF DURHAM.—At a recent Convocation the following degrees were conferred:—

Doctor of Medicine for Practitioners of Fifteen Years' Standing.—Percival Henderson and Ernleigh G. D. Milsom.

Bachelor of Medicine and Bachelor of Surgery.—Elizabeth M. Anderson, Siegfried Annecke, Kathleen A. M. Ayton, Dorothy I. Brown, Alfred H. F. Cole, Joseph Davis, William H. Denholm, Charles F. Fairlie, John Farnilton, Bertha Flintoff, Donald R. C. Grey, James B. Hartley, Robert E. Holme, Harold V. Ingram, Alan G. Ogilvie, Frank P. Rust, and John Stokoe.

Licence in Dental Surgery.—Frederick J. Gilbertson.

UNIVERSITY OF LIVERPOOL.—Vice-Chancellor J. G. Adams, in his address to the new graduates of the University of Liverpool on Dec. 17th, said that the mere obtaining of a degree of bachelor was insufficient for a student who wished to make his mark in the world and to serve his country. More and more was it necessary, he said, especially in science, for a man or a woman to undertake a period of special work and special research. For the first time the University now conferred the degree of Master of Orthopaedic Surgery. The degrees of Bachelor or Master in Medicine and Surgery qualified men and women to be practitioners of medicine, but for those who wished to specialise, the preparation was inadequate. If a man was interested in a particular branch—and the number of specialists in medicine was increasing year by year—the only way he had of showing himself an expert, and it was a most imperfect way, was by his joining the staff of one of their large hospitals and then awaiting an appointment as one of the members of that staff. The universities of this country did not offer any special training to such a man in his particular subject, and did nothing to show to the public that he was thoroughly well trained.

GUY'S HOSPITAL.—The bicentenary service of commemoration will be held in St. Saviour's Cathedral, Southwark, London, on Tuesday, Jan. 6th, at 12 noon.

CHRISTIANIA, the capital of Norway, will from Jan. 1st, 1925, resume the ancient name of Oslo, borne by the capital founded by Harold Haardrade in 1058, which was destroyed by fire, and replaced in 1654 by Christian IV. of Denmark.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—From Jan. 5th to 31st the Royal Eye Hospital (Southwark) will hold a course in Ophthalmology, consisting daily of the exhibition of clinical cases, followed by a lecture on Important Diseases of the Eye. There will be a special course in the Diagnosis and Treatment of Common Diseases of the Nervous System at the West End Hospital for Nervous Diseases from Jan. 5th to 31st. The course will take place in the Out-patient Department at Welbeck-street. Dr. Porter Phillips and Dr. Thomas Beaton have undertaken a series of nine lecture demonstrations on Psychological Medicine, beginning on Jan. 6th. Copies of the syllabus may be obtained on application to the Secretary to the Fellowship, 1, Wimpole-street, London, W. 1.

THE NEW YEAR HONOURS.

A SHORT list of New Year Honours reaches us as we go to press; it includes the names of five members of the medical profession on whom a Knighthood has been conferred. They are Dr. John Campbell, senior surgeon to the Samaritan Hospital, Belfast; Dr. T. Morison Legge, Medical Inspector of Factories, Home Office; Mr. Holburt J. Waring, formerly Vice-President of the Royal College of Surgeons of England and Vice-Chancellor of the University of London, surgeon to St. Bartholomew's Hospital; and Prof. Gowland Hopkins, Professor of Biochemistry in the University of Cambridge. Dr. Henry J. F. Simson, obstetric surgeon, West London Hospital, receives the K.C.V.O. We tender our congratulations to our justly distinguished colleagues.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Wednesday, Jan. 7th.

SURGERY: at 8.30 P.M.

Papers:

Mr. Geoffrey Keynes: Fat-Necrosis of the Breast.
 Mr. H. S. Souttar: Carcinoma of the Oesophagus.

Thursday, Jan. 8th.

TROPICAL DISEASES AND PARASITOLOGY: 5.30 P.M.

Lieut.-Colonel Sir Leonard Rogers: Points of Resemblance in the Epidemiology and Treatment of Leprosy and Tuberculosis.

Dr. Nathaniel S. Lucas: Some of the Infections of Captive Animals.

Dr. Lucas will show Microscopic and other Specimens to illustrate his Paper.

COMPARATIVE MEDICINE } Members of these Sections are
 DERMATOLOGY } cordially invited to attend this
 EPIDEMIOLOGY AND }
 STATE MEDICINE } meeting.

OBSTETRICS AND GYNÆCOLOGY: at 8 P.M.

Specimens:

Mr. A. C. Palmer: Primary Carcinoma of the Urethra in a Woman aged 56.

Mr. W. McK. McCullagh: Two Specimens of "Pseudo-Ovarian Cysts."

Paper:

Mr. J. Preston Maxwell (Peking): Osteomalacia in China (illustrated by means of photographs and lantern slides).

NEUROLOGY: at 8.30 P.M.

Paper:

Dr. R. M. Stewart: On a Case of Organic Spinal Hemianesthesia, showing the Persistence of a Form of Sensation hitherto undescribed, and the Occurrence of Allocheiria and Heteresthesia.

Friday, Jan. 9th.

CLINICAL: at 5.30 P.M. (Cases at 5 P.M.)

Cases will be shown.

OPHTHALMOLOGY: at 8.30 P.M. (Cases at 8 P.M.)

Papers:

Dr. S. Russ and the President (Sir Arnold Lawson): A Note on the Influence of Ultra-violet Radiation of Nocturnal Animals.

Mr. F. A. Williamson-Noble: Inflammatory Pseudo-tumours of the Orbit.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, London, W.

MONDAY, Jan. 5th, to SATURDAY, Jan. 10th.—ROYAL EYE HOSPITAL, St. George's-circus, Southwark, S.E.

Lectures and demonstrations on Diseases of the Eye. Daily, at 3 P.M., clinical cases, followed at 5 P.M. by a lecture.—WEST END HOSPITAL FOR NERVOUS DISEASES, 73, Welbeck-street, W.

Intensive Course in the Diagnosis and Treatment of Common Diseases of the Nervous System. Daily, at 5 P.M., lectures, including clinical demonstrations upon selected cases.—BETHLEM ROYAL HOSPITAL, St. George's Fields, S.E.

TUESDAY and SATURDAY, at 11 A.M. Lecture demonstrations by Dr. Porter Phillips and Dr. Thomas Beaton.

ROYAL DENTAL HOSPITAL OF LONDON POST-GRADUATE LECTURES.

FRIDAY, Jan. 9th.—5 P.M., Mr. E. Rhodes: Some Clinical Aspects of X Rays in Dental Practice.

WEST KENT MEDICO-CHIRURGICAL SOCIETY.

FRIDAY, Jan. 9th.—8.45 P.M., Clinical Meeting at the Miller General Hospital, Greenwich, S.E.

MANCHESTER MEDICAL SOCIETY.

WEDNESDAY, Jan. 7th.—4.30 P.M. (at the University of Manchester). Dr. J. M. W. Morison: Radiography of the Heart; Dr. R. Ollerenshaw: Surgery of the Astragalus; Dr. G. J. Langley: The Use and Abuse of Digitalis.

ST. MARY'S HOSPITALS, MANCHESTER, POST-GRADUATE LECTURES (at Whitworth-street, West Branch).

FRIDAY, Jan. 9th.—4.30 P.M., Dr. H. Clifford: Some Causes of Post-Climacteric Haemorrhage.

Appointments.

DELAFIELD, M. E., M.B. Camb., D.P.H., has been appointed Acting Head of the Department of Hygiene and Public Health, University College, London.

HANNA, W., M.D., B.Ch. Belf., D.P.H., Deputy Medical Officer of Health for the City and Port of Liverpool.

JACKSON, W. A., M.D. Liverp., Medical Officer of Health for the Compstall Urban District.

LOW, R. BRUCE, M.R.C.S., L.R.C.P. Lond., Medical Officer to the Welsh Board of Health.

MARSHALL, R., M.D. Durh., Hon. Physician to Noble's Isle of Man Hospital and Dispensary.

The Royal National Orthopaedic Hospital: CLARKE, J. J., M.B. Lond., F.R.C.S. Eng., Honorary Consulting Surgeon; JONES, A. R., F.R.C.S., Honorary Surgeon; and PERKINS, GEORGE, M.Ch. Oxf., F.R.C.S. Eng., and HIGGS, S. L., B.Ch. Camb., F.R.C.S. Eng., Honorary Assistant Surgeons.

Certifying Surgeons under the Factory and Workshop Acts: BARRETT, C. P., M.R.C.S., L.R.C.P. Lond. (Folkestone); MCCLELLAN, A. G. (Cinderford); and BATE, J., M.R.C.S. (Bethnal Green).

Vacancies.

For further information refer to the advertisement columns.

Adelaide University.—Marks Lectureship in Applied Physiology and Sheridan Fellowship. £750.

Belfast, Joint Nursing and Midwives Council, Northern Ireland.—Examiners of Midwives.

Bermondsey Borough.—Asst. M.O. for Maternity and Child Welfare. £600.

Birmingham and Midland Eye Hospital.—Res. Surg. O. £150.

Bristol Mental Hospital.—Second Med. Asst. £400.

Cape Town University.—Asst. to Prof. of Bacteriology. £500.

Chiswick Hospital, W.—Hon. Med. O. in charge of X Ray Dept.

Derbyshire Royal Infirmary, Derby.—Hon. Dent. S.

Hampstead General, &c., Hospital, Haverstock-hill, N.W.—Electro-Therapeutist. £50.

Harrogate Infirmary.—H.S. at rate of £150.

Hospital for Consumption and Diseases of the Chest, Brompton, S.W.—H.P. Six months. £50.

Liverpool Port Sanitary Authority.—Asst. Port M.O. £700.

London Homoeopathic Hospital, Great Ormond-street, W.C.—Res. M.O. £100.

London Jewish Hospital, Stepney Green, E.—Clinical Assts.

Lord Mayor Treloar Cripples' Hospital and College, Alton, Hants.—Second Asst. Res. M.O. £250.

Manchester Royal Infirmary.—H.S. to Aural, &c., Depts. at rate of £50.

Manor House Hospital, Golders Green, N.W.—Jun. H.S. £150.

Mount Vernon Hospital for Tuberculosis, &c., Northwood, Middlesex.—Asst. Res. M.O. at rate of £200.

National Hospital for the Paralyzed and Epileptic, Queen-square, W.C.—Hon. Anaesthetist.

Northampton General Hospital.—Third H.S. at rate of £150.

Nottingham General Hospital.—Res. Cas. O. at rate of £200.

Parish of St. Mary, Islington Infirmary, Highgate Hill.—Asst. M.O. £350.

Pendleton, Infectious Diseases Hospital, Ladywell Sanatorium.—Asst. R.M.O. £350.

Queen Mary's Hospital for the East End, Stratford, E.—Hon. Dental S.

St. Mary's Hospital for Women and Children, Plaistow, E.—Hon. Asst. P.

Stoke-on-Trent, North Staffordshire Infirmary.—H.S. £150.

Swansea County Borough.—Asst. M.O. £600.

Swindon Borough Education Com.—Oculist. 2½ guineas per session.

Sydney University, New South Wales.—Professorship of Obstetrics. £1100.

Victoria Hospital for Children, Tite-street, Chelsea, S.W.—H.P. and H.S. Each at rate of £100.

West London Hospital, Hammersmith-road, W.—Hon. Med. Registrar. £100. Also Hon. Obstet. Reg.

West Riding Mental Hospital, Menston, near Leeds.—Fourth Asst. M.O. £400.

The Chief Inspector of Factories, Home Office, S.W., gives notice of vacancies for Certifying Surgeons under the Factory and Workshop Acts at Ayton, in the County of Berwick; at Bovey-Tracey, Devon.

Notes, Comments, and Abstracts.

INDIVIDUAL INSURANCE IN THE FUTURE.¹

By HAROLD S. BEADLES, M.R.C.S.,

CHAIRMAN OF THE WEST HAM INSURANCE COMMITTEE.

THERE is not the least doubt that as time goes on the public services provided under the National Health Insurance Act are unfolding to the view of the student of social affairs a vista of health activity, more beneficial in its results than the promoters of the Act dared to anticipate at its inception. In spite of the many vicissitudes suffered by National Health Insurance administration since 1911—arising mainly out of the war—the financial assistance and medical attendance and treatment provided thereunder, has clearly demonstrated that with steadfastness of purpose, and the power of careful organisation, there is a possibility of achieving results in this phase of human life which must not be ignored by those responsible for the welfare of the community, if the peoples of the more thickly populated areas of the country are to be rendered capable of withstanding the unnatural strain put upon their bodies and minds by the present artificial existence known as modern civilisation. The elements of insurance have been provided for 15,000,000 persons as against 5,000,000 previously insured voluntarily. Nevertheless, we are even now only in a position to discern the fringe of the true health standard. The full splendour of good health can only be enjoyed by the establishment of well-defined and effective relationship between the various participles now wandering more or less haphazardly around the central and local administration of public affairs. The systems of health and public welfare administration which have been built up in this country during generations past, each very good in its service of that particular need which caused its creation, have now become much too numerous for the individual, whom they are intended to benefit, to thoroughly understand and use to the best advantage. The creation of funds for the operation of such systems is to-day also a matter of considerable complexity. The operation of the National Insurance Act has unmistakably demonstrated that continuance of this multiplicity of systems and complexity of finance is entirely unnecessary. It has shown the necessity of providing complete insurance for workers without the possibility of such workers being at any time "out of benefit." That which has acted so smoothly in health and unemployment insurance during the past 12 years can operate equally effectively and efficiently in other public welfare services. There are taxes for some services, local rates for others, precepts, rates and voluntary subscriptions for others, whilst compulsory contributions in other forms now play a big part in the social scheme. A number of the services have bases of incidence of charge peculiar to themselves and differing materially from those of others.

Imperial and Individual Services.

It is claimed that there is no need for all these varieties. All public services might well be divided into two main categories—viz., (a) Imperial—i.e., those applicable to the community as a whole, and (b) individual—i.e., those applicable to and enjoyed by the individual particularly. In the former there would be included the navy, army, air force, and other defence services, diplomacy, government (central and local), police protection and allied services, education, construction and maintenance of roads, water-supply, housing, drainage and sewage, sanitation, prevention of pollution of air, water, and food, control of agriculture, shipping and transport, medical research, and many others. Under (b) would be grouped financial assistance in time of sickness and accident, maternity and unemployment, widows and orphans and old age pensions and allowances, medical attendance and treatment in the fullest sense, including all institutional, dental, ophthalmic, and specialists' services and nursing. It is the (b) group with which I am now dealing. To-day all political parties have announced their intention to alter and extend national insurance against sickness, unemployment, and accident, and to coördinate measures to these ends with provision for old age, widowhood, and orphanage. Yet of all the schemes so far expounded not one would seem to aim at total insurance for all social "individual" services.

Different Payments for Different Conditions.

The Insurance Acts have further shown the inequity of having different payments for different conditions. It is

¹ An address delivered to the West Ham Insurance Committee.

Births, Marriages, and Deaths.

BIRTHS.

LAING.—On Dec. 21st, 1924, at a nursing home in London, the wife of Major F. R. Laing, R.A.M.C., of a daughter.

MACLEAN.—On Dec. 25th, at Newcastle, Staffordshire, the wife of Dr. Bruce Maclean, of a daughter.

MARRIAGES.

FORBES-PYMAN.—On Dec. 19th, 1924, at Holy Trinity, Brompton, Dr. A. Keith Forbes, M.C., to Esther Pyman, daughter of Mr. F. H. Pyman, Fitzjohn's-avenue, Hampstead, and Dunsley, Whitby.

DEATHS.

CLARKE.—On Dec. 27th, 1924, at Montana, Switzerland, Cecil Clarke, M.D., M.R.C.P.

HAMMOND.—On Dec. 20th, 1924, William Hammond, M.R.C.S., L.R.C.P., of Park Drive, Golders Green, N.W., many years Chief Librarian to the Grand Lodge of England, aged 76.

PENTLAND.—On Dec. 21st, 1924, suddenly, in London, the result of an accident, Charles James Pentland, M.D. T.C.D.

THORPE.—On Dec. 19th, 1924, at Frogham, Fordingbridge, Hants, Arnold Edward Thorpe, L.R.C.P. & S. Edin., aged 63.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

difficult to see why, if sickness is to be the subject of insurance, the benefit derived therefrom, when sickness falls upon the insured, should be something short of the benefit derived from employment. Sickness places a far greater strain upon the household exchequer than good health. Therefore sickness pay should at least bear adequate proportion to good health pay. At present the sick pay is 15s. per week, whilst unemployment averages 50s., compensation for accident 30s., and that for old age 10s. Similar benefits of insurance should apply to old age, unemployment and the other ills to which the great majority of the working people are heir. Subject, of course, to family responsibilities, these should be equal to say 30s. for the man: when it would be unnecessary to distinguish whether a person is prevented from working by illness, unemployment, accident, old age, or any other disability. The standard of living given by the insurance benefits should be regulated according to the disability which the benefit is created to counteract. At the same time all the necessary means available for the removal of the disabilities insured against should be brought into full operation on behalf of the individual as part of the insurance scheme. These would include domiciliary medical attendance and treatment, institutional treatment—surgical and otherwise, and nursing, and also the finding of employment. National insurance must primarily be for the benefit of the community and not for the individual, and for this reason the premium should cover all time of unemployment from whatever cause it may owe its creation. It must include all those who now come under the Poor-law. Many of these are the same people, temporarily unemployed, whilst others are unemployable for various reasons; but the State cannot afford to leave these out, if it desires a healthy nation. Some of the unemployable are now the greatest danger to the community.

Administration Problems.

The funds required for the provision of these individual services should be raised in manner somewhat similar to the present system of national insurance so far as they would be collected through the medium of stamps purchasable at the post office. There should, however, be one form of stamp for all purposes, the face values being graduated from a minimum to a maximum by not less than one penny. The primary function of the stamped card would be the check it would furnish upon the proper payment of contributions on behalf of the person employed. Contributions should be payable in respect of every person reaching employment age—viz., at the expiration of his or her school age; and should continue to be payable until either the age of 65 is reached—when the old age pension would be payable—or until certain agreed earning has been attained, or until proof that a certain standard of living was assured by private means. Such contributions should be at a rate per pound of earnings, probably sixpence to the worker, and could be charged in suitable proportion between the State, the employer, and the employed. During periods of unemployment through sickness or otherwise, the rate of contribution should be paid by the State and the insured person concerned, out of his cash benefits. The State's contribution to the benefits and administration, representing the State's interest in the social welfare of the individual, would be drawn from the funds derived by special taxation and revenues for imperial purposes, or as a first charge upon income tax.

The monies accumulated by the sale of stamps would pass through a central fund, controlled by the State, to local pools controlled by the administering local authorities.

How to Meet Expenses.

It is estimated that about £280,000,000 per annum would meet the expense of the personal services requirements of the community. This figure being arrived at as follows: Health £94,500,000, employment £85,500,000, both including cash payments, pensions (old age, &c.) £100,000,000. To meet this annual charge a levy of 2s. 6d. would have to be made in respect of every £1 earned in the country; apportionable between the State, employer, and insured person. This seems at first sight to be a large proportion of the country's wages bill, but it must be remembered that under this scheme the poor relief rates, a considerable proportion of the ordinary local rates, hospital contributions, and other central and local taxes and rates would disappear, whilst the present contributions under the Health and Unemployment Insurance Acts would also be merged. Moreover, much of the present wasteful method of collection of revenues—State and local—would be swept away.

Control and Supervision.

The State would control the collection of funds and supervise the apportionment thereof amongst the local authorities responsible for the actual administration of the benefits. The local authorities referred to should be constituted mainly of persons appointed by and from the present councils of counties and county boroughs supplemented by persons

appointed by such councils and nominated from various interests concerned with the working of the scheme, due regard being paid in the making of such appointments to experience acquired by the persons selected in the public services which are to be absorbed thereunder. Medical benefit is at present administered by insurance committees, but only general practitioner attendance is provided for most of the insured and then only "if in benefit." Additional benefits are provided by some approved societies for some of the insured. It is now clear that the only way to provide complete medical attendance for the whole community is to place it under the control of one body, not separate approved societies or the present insurance committees, but an "ad hoc" committee of the county or borough council on the lines of the educational committees—which committee could administer all health matters and properly coordinate them. When contributions are taken compulsorily from a portion of the community, the contributors have a right to expect to be provided with equal benefits and on equal terms. The position of the deposit contributors is a serious menace to the general health, and so long as there exists a number of societies approved for the purpose of administration and giving different benefits to their members the name of "National" becomes a farce. The working of the Act has shown some of us that we cannot continue permanently to have such societies approved and that here again we shall have to set up committees of county and borough councils, which committees will administer not only health insurance but all other forms of social insurance, including those for sickness, accident, unemployment, old age pensions, and widows' pensions, when there will be no necessity for the present Poor-law system.

Our thanks are due to the approved societies for all the work they have done in the past, the friendly societies as the pioneers, and the great industrial insurance companies for the assistance of their wonderful organisations, but we and they must recognise that the time has come for changes marking the next stage in the development of the great social amelioration; and that they, as well as you as members of insurance committees, must give way to some administrative body more comprehensive in its constitution and more effective in its power.

PUBLIC HEALTH OF GIBRALTAR.¹

THE "fixed civil population" of Gibraltar (i.e., the number of British subjects) at the end of 1923 was estimated at 16,165; in addition some 10,000 aliens and 1500 British subjects resident in La Linea come into Gibraltar daily. The birth-rate in 1923 (for the fixed population) was 22.57, and the death-rate 17.63 per 1000. The former was lower than in the preceding years since 1917, when it had been 22.3. The latter was lower than in the five years preceding, except 1921, when it had been 15.74 per 1000. With regard to the prevalence and control of infectious diseases, it is stated that not a single case of small-pox was notified throughout the year. Primary vaccination is compulsory, and since 1906 all children on arriving at the age of 12 years have to be revaccinated. "The population of Gibraltar is now one of the best protected communities in the world against small-pox, and although constantly exposed to the menace, a case of small-pox rarely occurs in Gibraltar." There were 19 cases of enteric fever, with two deaths; four cases in addition were landed from the Bay (one fatal). The local cases (with one exception) were all sporadic, and no direct evidence was obtained as to the cause. The water-supply was not incriminated. Diphtheria (21 cases, two fatal)² was more prevalent than in any year of the decennium (1914-23) except 1922, when there had been 30 cases with three deaths. Only 31 cases of measles were notified (two fatal), in contrast with the considerable prevalence in 1921 and 1922, when the cases had numbered 388 and 305 respectively. Twelve cases of Mediterranean fever were notified (one fatal). From 1914 to 1922 inclusive the total cases had only numbered 24, with two deaths. The notifications of pulmonary tuberculosis (48) were more numerous than in any year since 1913, when they were 63; but the deaths numbered only 22, a lower figure than in any of the ten years preceding. Influenza of a mild type prevailed throughout the year. The cases numbered 545, of which 394 occurred in the three months April to June; there were only two deaths in all. Scarlet fever appeared in epidemic form during 1923, for the first time, as far as can be ascertained from the city records. The cases numbered 218, of which 188 were under 15 years of age. The disease was generally of a mild type, and only five cases were fatal (2.3 per cent.). The cause of the outbreak was not clear. It was probably imported. A large amount of milk is brought into Gibraltar from Spain, but all such milk is boiled

¹ Gibraltar Garrison Library Printing Establishment, 1924.

² As stated on pp. 28 and 32. On p. 31 the deaths are stated as three.

before being distributed. In regard to the infantile mortality Lieut.-Colonel W. C. Smales, D.S.O., R.A.M.C., who presents this report, considers that the year was "an unsatisfactory one," the ratio being 109.5 per 1000, as compared with 69 for England and Wales (1923); wasting diseases and diarrhoea were the chief causes of death. A child welfare centre has been of great service, granting assistance to poor families, providing milk or virol, and instructing mothers in the preparation of food, nursing, &c. Under the "Destitute, Sick, and Tuberculosis Scheme" some 224 families have received outdoor relief, a large quantity of meat and milk has been distributed, and some 700 visits paid by the nurse.

SOMALILAND.

A REPORT on this British Protectorate (which contains about 68,000 square miles, and has a population consisting mainly of Mohammedan people estimated at 300,000) for the year 1923 has been issued by Mr. H. B. Kittermaster, O.B.E., secretary to the administration. It states that owing to the excellent rainfall throughout the year there has been a very small influx of natives into the coast towns during the winter months, as compared with previous years, and this accounts for the fewer cases admitted to hospital. The health of the European population was good, and there were no deaths or invalidings; 1100 in-patients and 22,817 out-patients were treated in the hospitals of the Protectorate—viz., for scurvy, 6; ulcers, 4000; malaria, 205; relapsing fever, 96; small-pox, 0; influenza, 50; dysentery, 34; diarrhoea, 360; tuberculosis, 215; whooping-cough, 63; measles, 10; chicken-pox, 32; syphilis, 946; gonorrhoea, 266.

THE PACKING INDUSTRY.

A SERIES of lectures delivered at the University of Chicago in the spring of 1923 have been published in book form.¹ They aim to give a generalised survey of the American meat packing industry, its background, its service, and its operations, intended for the instruction and assistance of those interested in this industry. They purport to replace by systematic instruction what the author of the introductory lecture describes as the casual mouth-to-ear system. They form part of the structural development programme of the Institute of American Meat Packers. The ground covered includes live-stock, the history and general economics of the packing industry, the packing plant; two lectures on what are termed "operations," an expression covering the conversion of the raw animal to the marketable food, the finance of the industry, science in the industry, and distribution of meat products.

The book contains little or nothing of direct interest to medical readers, but is full of information of a curious kind. Those who wish can learn the proper method for chilling hogs, the significance of "frozen credits," and that the well-meaning people who launched an eat-no-lamb campaign on the grounds that no lamb now would mean more mutton hereafter were guilty of an economic waste. It is fitting that from Chicago should emanate a glowing tribute to the hog—"that noble vertebrate, the hog—a most excellent fellow, not merely from a cold economic standpoint, but as a personality. Though calmly independent, he is always approachable; he does not curry favour; he is never forward; he lives and lets live. He is thrifty, but believes there is a time for rest and leisure. Democratic in his tastes and instincts, he would be a Liberal in politics. He accepts man as his friend and equal—truly a great and magnanimous fellow." The lecture upon science in the packing industry is of interest, and shows that science came into the industry late in the day long after it had been established on empirical lines. In consequence, we are told that much of it was thoroughly unsound and irrational, and could have been corrected at the start by a reasonable application of scientific methods. While chemistry and physics are given an important place, bacteriology is scarcely mentioned and would appear to be neglected.

SANITARY PROBLEMS OF TROPICAL AMERICA.

As official delegate to the International Conference on the sanitary problems of tropical America, held in Kingston, Jamaica, July 23rd-30th, 1924, Dr. A. Agramonti gives a short account of his experiences in the *Revista de Medicina y Cirugía de la Habana* of Oct. 10th, 1924. The Conference seems to have owed its origin to the initiation of Dr. W. E. Deeks, the P.M.O. of the United Fruit Company—a great American trust with branches all over tropical America. To him and to Dr. G. Vincent, head of the International Committee of the Rockefeller Foundation, Dr. Agramonti pays a high tribute of praise. The usual tropical subjects were discussed—malaria, yellow fever, amebiasis, as well as various problems in general medicine. The point which seems

to have struck Dr. Agramonti most was the general agreement that every case of malaria must be treated on its merits and that no standard method, as taught in the United States, is possible. There seems also to have been a consensus of opinion that "alastim" is only a modified form of variola, though the Jamaican doctors dissented. Dr. Agramonti compares the medical institutions of the Jamaican Government unfavourably with those of Havana, excepting only the mental hospital. After the Conference the delegates visited officially Honduras and Guatemala.

ANTHOCYANINÆMIA.

THE condition of anthocyaninæmia, and the allied one of anthocyaninuria, give rise to a symptom almost as alarming as their names, for the patient's urine is coloured a brilliant red. However, anthocyanin is nothing more than the name of a pigment found in the common beet. Dr. H. O. Ruh and J. A. Garvin, of Cleveland, Ohio, U.S.A., have seen¹ as many as 30 children in whom the only complaint was red or "bloody" urine, in each case due to eating beets. Attempts to produce the condition experimentally were eventually successful. They find that the production of anthocyaninæmia depends not only on the quantity, but also on the quality of the beets ingested. Presumably, although no such case is recorded by the authors, a patient whose urine happened to be alkaline and who ate sufficient beets, would complain of a bright blue urine, for the pigment is an unstable compound of the nature of a glucoside, and has been suggested as an indicator on account of its property of changing colour according to the acidity or alkalinity of its solution.

COLOURED BOOKS.

To the Editor of THE LANCET.

SIR,—I notice that when referring to various Government publications in your columns you occasionally speak of them as blue books, white books, green books, and so on. My ignorance of the ways of officialdom prompts me to ask whether these chromatic titles must vary to express the truth as regards H.M. publishers' taste in binding, or whether the term "blue book" is not sufficiently generic to include all official motley. To put the question concretely: can a blue book be pink?

Yours faithfully,

PUZZLED.

Dec. 28th, 1924.

*** The term "blue book" is often used to cover publications of different hues. Perhaps it should not be so employed.—ED. L.

TEXT-BOOKS AND INSTRUMENTS IN RELATION TO INCOME-TAX ASSESSMENT.

THERE appears to be a doubt in the minds of some of our readers as to claiming allowance in their income-tax schedule in respect of expenditure on books and instruments for professional purposes. The following exchange of letters is typical:—

Practitioner to H.M. Inspector of Taxes.—Last year you told me in conversation that a claim for allowances of income-tax in respect of the purchase of books or instruments was not allowable except in the case of renewals, and that no books or instruments purchased for use for the first time would be allowed for. I have recently been given to understand that this is not so. The Regulation appears to make no reservation or exception but to apply to any books or instruments which are required for professional purposes.

H.M. Inspector of Taxes to Practitioner.—I beg to inform you that renewals and replacements of books and instruments are only allowable for income-tax purposes. Additions, as distinct from renewals and replacements, are not allowable.

The opinion of the Inspector of Taxes is in accordance with the present law and practice on the point. No allowance is made for additions or improvements, but only in respect of repairs, renewals, and replacements.

WHO WAS JACQUES?

SURGICAL literature frequently uses the name spelt phonetically Jakes to denote a flexible catheter, but hesitates how to spell the name. The catalogues of surgical instrument makers contain numerous variants, sometimes in the same list. After considerable inquiry we learn that the right spelling is Jacques, and that the bearer of the name was head of the British rubber firm of Jacques, Coles and Fanshaw, now defunct. The catheter which goes by his name is of soft rubber, and is now made by other rubber firms in this country. So far as we can ascertain the name though French in form is not known in French literature, where the soft catheter goes by the name of Guyon.

A Surber

OF

PRESENT-DAY ELECTRO-THERAPEUTICS.

An Address to the Section of Electro-Therapeutics of the Royal Society of Medicine

By STANLEY MELVILLE, M.D. BRUX.,

M.R.C.S. ENG.,

PRESIDENT OF THE SECTION; RADIOLOGIST TO ST. GEORGE'S AND BROMPTON HOSPITALS.

THE DISCOVERY OF X RAYS.

LESS than 30 years ago—to be precise, on Nov. 8th, 1895—Prof. Rontgen, of the University of Würzburg, startled the whole of the scientific world by his announcement of the discovery of the new rays. Working as he was at the time on electrical discharges *in vacuo*, he noted, among other things, that paper coated with a layer of barium platino-cyanide fluoresced if brought near to an excited Crookes tube which had been covered with black paper. From this experiment he deduced the existence of certain rays which were able to traverse black paper and, by inference, other opaque bodies, and these rays were named X rays by the discoverer. No more striking example of evolution in a discovery of great scientific interest has ever been known. It was by no means a haphazard or accidental discovery, but the logical sequence of continued work in a perfectly orderly manner. Rontgen himself always admitted the ancestry of his discovery. In the first place, the great work of Sir William (then Mr.) Crookes, the stimulation of this work upon Prof. Jackson in designing focus tubes and experimenting with various salts for fluorescent screens, later the work of Lenard on cathode rays, and finally Rontgen himself. In a paper read before the Rontgen Society at one of its early meetings in 1898 by Mr. Webster, this debt to the earlier workers was handsomely acknowledged. "But for Crookes's early experiments," he said, "Jackson would not have experimented with his focus tubes and fluorescent screens, and but for both of them Rontgen would probably not have completed his discovery. I venture," he added, "to say that the Union Jack can be placed almost entirely over the discovery."

The inaugural address given by Prof. Silvanus Thompson at the newly-formed Rontgen Society in 1897 must have been very inspiring to his listeners. "November the 8th, 1895," he said, "will ever be memorable in the history of science. On that day, 'a light,' which so far as human observation goes, 'never was on land or sea,' was first observed. The observer, Prof. Wilhelm Conrad Röntgen. The place, the Institute of Physics in the University of Würzburg in Bavaria." Würzburg, a small university town of less than 50,000 inhabitants with a magnificent block of buildings, well endowed, and devoted to the study of physics, and contrast it with our own position at the same date. We have cause to be thankful that at any rate the realm of physics has now come into its own.

The first focus tube was constructed in this country in 1894, to the design of Prof. Jackson. To Mr. Campbell Swinton, F.R.S., we owe a great deal of experimental work, especially on his proof that the penetrative power of X rays was dependent upon the degree of exhaustion of the vacuum of the tube. It is interesting to note that the theories enunciated by Prof. Jackson have remained the basis for all gas tubes up to this day. Sidney Rowland, Special Commissioner to the *British Medical Journal* for the investigation of the application of the new photography to medicine and surgery, and the first editor

of the *Archives of Skiagraphy*, wrote as follows: "Whatever may be the scientific explanation of the exact character of the X rays, their discovery is invaluable to physicians and surgeons. By means of the new radiation it is now possible to render visible certain of the interior structures of the body, and their precise condition of disease or of health can be objectively demonstrated. Facts which heretofore could only be known or guessed at by a complicated system of inference are now *oculis subjecta fidelibus*." (I fear the cynic may laugh at the eye of faith, which we are still accused in some quarters as possessing.)

In the same paper he warns his readers to beware of many extravagant stories and reports, chiefly from transatlantic sources, as to the results of the Würzburg professor's discovery. It is interesting to read the correspondence columns in the earliest numbers of the *Archives*.

J. L. is advised that the minimum spark-gap required is 2 inches and that it is necessary to have a coil giving a nominal 3 inches.

J. L. P. is advised to wrap his plates in black paper and to push development to the utmost.

Ignoramus is told that he will recognise that his focus tube is working correctly when one half is fluorescing a yellowish green and the other half remains comparatively dark.

J. N. is advised to place the object to be skiagraphed as near the plate as possible, and the sage advice (equally necessary to-day) is given—namely, to treat the whole matter as a shadow in order not to go wrong.

EARLY ADVANCES.

Following rapidly upon Rontgen's discovery, medical men and others began to work with the new rays, and very soon names appear, names that are now household names, Thurstan Holland of Liverpool, Mackenzie Davidson, David Walsh, Hall-Edwards of Birmingham, and MacIntyre of Glasgow, among others. To show with what determination these pioneers set to work, it is interesting to note a paper written by Thurstan Holland in 1898. Between June, 1896, and Dec. 31st, 1898, he had taken no less than 728 skiagrams, working, as he tells us, with Apps-Newton coils giving 3.6 and 10 inch spark, using Watson's or Cossar tubes, and giving exposures varying from a few seconds to an hour. The tubes were placed at varying distances from the skin, from 4 to 12 or 14 inches. It is most interesting to learn from the lips of Thurstan Holland that during the whole of the period in question he had never seen the slightest damage of any kind, not even the removal of a hair, nor any redness of the skin.

In the earliest days attempts were made to demonstrate the presence of renal calculi. These attempts were apparently unsuccessful, for Mr. Henry Morris found that owing to the position of the kidney, close to the vertebral column, the depth of the cavity, and the thickness of the overlying tissues, it was impracticable to obtain a radiograph of renal calculi. Fortunately for the credit of radiography, just about the same time Thurstan Holland demonstrated successfully the presence of calculi in the pelvis of the kidney.

Discovery of Therapeutic Uses of X Rays.

Equally early the use of X rays as a therapeutic agent was begun, and cases of lupus and rodent ulcer were treated with success. Cases of epithelioid ulcer of the mouth were reported as doing well, especially in regard to alleviation of pain. A case of cancer of the stomach was treated, resulting in disappearance of pain and some diminution in the size of the tumour. Lortet and Genoud (reported in *Comptes Rendus*, 1896) gave an interesting account of their experiments on the effect of Rontgen rays in tuberculosis. Eight guinea-pigs were inoculated with the virus of tuberculosis. Of this number three were exposed daily for six weeks to irradiations. In the five not irradiated abscesses formed and the general health was deranged. In the three irradiated, no abscesses

were formed and the general health remained good. Two Italian physicians about the same time did somewhat similar research on guinea-pigs with intraperitoneal injections of cultures of human tubercle. Repeated experiments led them to the conclusion that exposure to X rays retards the development of tuberculous infection, chiefly by raising the body resistance.

Both these series of experiments at a somewhat later date were reviewed critically by Bergonié, of Bordeaux, and Teissier, of Paris. They came to the conclusion, however, that animals infected with tuberculosis, even if subjected for more or less long periods of time to the action of the rays, die for the most part, and without any appreciable modification of the lesions and without any retardation of the evolution of the disease.

I mention these experiments to show how much scientific work was being attempted in the early days and all in the right direction.

X Rays in Military Surgery.

I think I am correct in stating that X rays were made use of in military service for the first time in the Tirah campaign, and later with the Nile expeditionary force in the Soudan in the summer of 1898, in which campaign Surgeon-Major Battersby was in charge of the X ray work. In this campaign a modification of Mackenzie-Davidson localising apparatus was used with much success. "X rays," wrote Dr. Haughton, of Dublin, "have furnished the military surgeon with a probe which is painless, which is exact, and, most important of all, which is aseptic, qualities not possessed by the older, though ingenious, instrument bearing Nélaton's name."

As an instance of early difficulties met with in making the higher powers appreciate the necessity of X ray assistance in warfare, it is of interest to note the answers given in the House of Commons, when the question of supplying the Soudan expeditionary force was being discussed. Surgeon-Major Beever, who had been in charge of the X ray equipment during the Tirah campaign, had reported favourably on their use. A few days later, Mr. Brodrick, in answer to questions, replied that the senior medical officer had gone carefully into cases cited, and had been unable to trace any single case among the wounded where the apparatus would have been specially useful or in which an operation would have been more successfully carried out by means of the rays. The Director-General of the Royal Army Medical Corps, whose name I cannot at the moment trace, but he was a man whose name deserves the highest honour, brought the weight of his authority to bear, and, better counsel prevailing, the Soudan campaign was equipped with as good apparatus as was at that time to be obtained. Surgeon-Major Battersby's account is well worth reading.

DIFFICULTIES OF EARLY WORKERS.

Such, then, briefly, was the beginning of our work—of our great and absorbing specialty. Just a handful of enthusiasts working under great difficulties and with no little discouragement. Their apparatus was feeble for the most part; very soon they became aware of danger attending their work and this before any means of combating it was known. Considerable controversy took place as to the nature of the injurious effects of exposure to irradiations. These were described variously as being due to ozone, to particles of platinum, and even to heat. From time to time vexatious actions in the law-courts all but succeeded in arresting progress. In 1899 the first lawsuit was heard in Paris, the plaintiff claiming heavy damages for injuries as the result of exposure to X rays. Bardet (of La Pitié Hospital) stated at the time that if any responsibility is attached to the use of X rays they cannot be utilised. The question of individual susceptibility to X ray irradiation was much discussed at this time and as a direct result of the lawsuit. In spite of all the early difficulties, the pioneers

held on and have piled up a debt of gratitude which future generations will find it difficult to repay.

Possibly in nothing was the early radiologist more handicapped than in the paucity of literature. Such as there was would have been even more difficult to obtain but for the most excellent bibliography (and indeed much more than a mere catalogue of current literature) brought out by our friend C. E. S. Phillips. There were no Rutherfords or Braggs or Kayes in those days to help, and I think the joint author of that most illuminating book—"Radium, X Rays and the Living Cell"—must still have been in the chrysalis stage. The physicist was, I think, more interested in trying to solve the burning question as to the nature of the rays than in taking the line so material to the future of our work that we see to-day. The great controversy on the nature of X rays lay between those who (like Prof. Thompson), though non-committal, declared in 1896 that there was nothing in the effect known to be due to these rays that was inconsistent with their being a variety of light, and those other physicists, such as Goldhammer, who took the view that X rays were not of the nature of longitudinal light waves, but were ultra-violet rays of extreme shortness. Somewhere between these two views (as is often the case) lay the truth, and we know now that X rays are ether waves or disturbances of the ether akin to light, but with a wavelength some ten thousand times less than similar disturbances known as light.

We have passed from a position of doubt and uncertainty to a position of security. A properly equipped X ray department is a vital necessity to the hospital of to-day, and the keen radiologist is now a not unimportant member of the hospital staff. There is still much to be desired in some hospitals in this respect, but time, and, above all, the enthusiasm of the radiologist will set this right. Well known are the researches of men like Barclay, Hurst, Jordan, with Case, Carmen and Miller, from the other side of the Atlantic, on the alimentary tract; of Knox and others on radiation therapy; of our late friend, Hugh Walsham, on the respiratory tract (to whom, with Harrison Orton, we owe the first book on the subject). No longer has the radiologist of to-day to go out, like the Israelite of old, into the fields to gather stubble for his brick-making, but it is all provided for him in the shape of good straw, possibly more than he can find time to digest.

THE WORK OF THE ELECTROLOGIST.

I would that I felt competent to touch upon the work and the evolution of the other and equally important half of our section—I refer to the work of the electrologist. It is one of the curious anomalies of our day that not even was the great work of Lewis Jones sufficient to make hospital authorities recognise that the two branches of work must be separated. I have never been able to appreciate the reason—possibly it was because we were both utilising current from the electrical mains? Was it because there was a very limited number of men really qualified to take up the highly specialised work of the electrologist? Was it (I say it with bated breath) that they did not believe in either of us very much? Or was it analogous to the teaching of that great subject—forensic medicine—which was regarded as a subject that anybody could teach, and the lectureship was given to any member of the staff for whom no other work could be found? I know not. This I do know, that until the late war the necessary cleavage had not taken place except in certain of the larger schools. I only ask you to imagine where we should be had Cumberbatch and his associates, for instance, been so busy with X ray work as to leave them no time for their work on diathermy. How much the poorer should we not have been but for the labours of W. J. Turrell on the physiological aspect of electrical discharges and his theories on ionisation, and men like Bourguignon of the Salpêtrière? Ten years ago, I make bold to say, that such

a successful bi-lingual Congress as that held in 1922 would have been impossible, at any rate on the side of the electrologist and our brothers in other fields of physical medicine.

"Evolution," as has been well said, "is not a force but a process, not a cause but a law." Its progress is slow, but it follows upon definite lines. In nothing has the gradual evolution of radiology been better demonstrated than in the growth and equipment of an X ray department. No longer is a cupboard in a basement considered satisfactory for modern requirements. Much improvement still is necessary in many places, and several factors have recently been at work giving the necessary impetus towards the provision of properly ventilated, efficiently protected and roomy X ray departments.

Of these factors two in particular I may mention. First, the invaluable work and research undertaken at the National Physical Laboratory by Drs. Kaye and Owen. Secondly, the recent decision of the Home Office to include or rather to extend the provisions of the Workmen's Compensation Act, 1906, to include and cover certain injuries and diseases caused by exposure to X rays or other radio-active substances. Well do I remember being shown two largish cupboards which had been allocated for the X ray department at the King George Military Hospital in 1915. They were literally nothing but cupboards, without any outside ventilation whatsoever, but they were conveniently near to the operating theatres. Fortunately my colleagues, Ironside Bruce and Harrison Orton, saw eye to eye with myself, but we had to stand much criticism about our pig-headedness in insisting upon the excellent and well-ventilated department we eventually secured. Shall I tell you how Thurstan Holland annexed, first the large dispensary at the Royal Infirmary, Liverpool, then the great recreation hall, in which other members of the section as well as myself remember playing Badminton in our leisure time as house physicians? The last time I visited Liverpool I found other large portions of the hospital had been annexed; indeed, I believe it was his intention to have the hospital attached to the X ray department—a very laudable scheme.

Those of us who were privileged to visit the new X ray department of the Royal Infirmary, Manchester, had their eyes very widely opened. I could wish that Dr. Barclay would see his way to inviting the chairmen and secretaries of the London hospitals and demonstrate to them his conception of what a modern department should be. In fairness, however, let me say that only lack of funds, and what is perhaps more serious—namely, lack of space, militate against our getting what we require.

One of the most interesting of the forward movements of to-day has been that which owes its conception to the farsightedness of our senior secretary. Together with Prof. Stopford, Dr. Woodburn Morison has equipped a room for X ray study in the Anatomical Schools of Manchester University. He was appointed lecturer under the scheme, and has drawn up an excellent scheme of lecture-demonstrations. Dr. Salmond gave us a very good account last session of similar work being done at University College, and I think we may look forward to the time when, in all our great medical schools, the subject of applied anatomy will be taught from the radiological standpoint also.

THE PHOTOGRAPHIC SIDE OF THE WORK.

At times I am inclined to wonder whether from the very beginning we may not have been wrong in allowing the purely photographic side of our work to assume a position of too great importance. I refer in particular to the routine custom of making prints—an unfortunate custom, which has given the patient the impression that in some way or other he had a vested interest in the radiograph as part of the contract. I do not wish to be misunderstood. In the early days one has to remember that the discovery of X rays caused the very greatest commotion

throughout the entire community, and the patient naturally desired a memento to show to his admiring relatives and friends. We are, however, medical men and women engaged upon the definite and serious work of assisting in diagnosis. Anything that tends to lower our prestige or to emphasise any other aspect of our work is, in my submission, to be deplored.

Plates or films after all are only of use for two purposes: (1) to aid us in arriving at correct interpretation; (2) to enable us to give ocular demonstration to those of our colleagues who ask for our help. Sooner or later the routine giving of prints leads to undesirable results, as most of us have experienced. Many of us have had to face more or less unpleasant arguments affecting the legal ownership of plates, and although the law of copyright is very definite, such discussions ought never to arise. I do not wish to labour the point unduly, although it is a subject upon which I feel strongly. Instances occur to many of us of the undesirability of the practice. I think, however, the pathologist in his generation was wiser than ourselves—the children of light. Can you conceive of the public desiring a microscopic slide, or even a microphotograph, say, of a section of a tumour? Yet this is quite a logical analogy. The latter would be about as helpful to a patient as would be the print of an abnormal chest.

I fear there are causes upon which I cannot dwell which militate against the counsel of perfection to which I have referred. I can only hope that my colleagues will think over the pros and cons of the matter.

EDUCATION IN ELECTRO-THERAPEUTICS.

As will readily be appreciated, the radiologist of to-day is in a much better position than was his predecessor. At the beginning of the war, we, in England, at any rate, were not prepared on the radiological side. Many of the younger men with stout hearts but (I know they will not mind my saying so) with colossal ignorance, stepped into the breach. At the conclusion of the war many of these men decided to take up the subject seriously, but they found very speedily that war conditions and the requirements of the civil radiologist were very different things, and they were but ill-equipped for the work. There was no kind of systematic teaching, and many of us know how difficult it was to try and cope with the men who visited X ray departments, hoping to acquire knowledge. Thus it was that the Universities of Cambridge and Liverpool decided to institute a special diploma. I am well aware that the multiplication of diplomas is undesirable. This much, I will say, that the man or woman who takes the trouble to work for the diploma is a much better man than his neighbour who does not do so. It is obvious that it is impossible for anyone to learn the whole of a vast subject in the six months' course allotted to it, but he will gain a good grounding in the physics of the subject and the general routine of X ray and electrical work. With such a grounding he will soon learn by experience, and experience, after all, is but the sum total of our own "and other people's" mistakes. At both Universities already a large number of men and women have taken the diploma, and we can leave the future of our work with great confidence in their hands.

"Oh! that mine enemy would write a book," as the cynic remarked. Fortunately, there is no ill-feeling among the members of our section, and such a condition could not exist. I am, however, above everything especially interested in the educational side of our work, and I should like to relieve my mind of a few comments respecting our text-books. For the beginner, at any rate, may I suggest that there is frequently something lacking in the dogmatic teaching which he desires, especially in regard to "differential diagnosis." Knox's excellent work will naturally be studied by everybody. In the recent edition of Muir's "Manual of Practical X-Ray Work" a great step forward has been taken in this essential.

I should like to stimulate Bythell and Barclay to give us a new edition of "X-Ray Diagnosis and Treatment." The first edition was so full of good stuff that I feel sure a new edition is overdue. Some more specialised text-books are needed. I wonder if the time has not arrived when it might not be possible and advantageous to have a carefully edited book comprising the lectures already given in preparation for the diploma. A recent work by Wesseler and Jaches has been published in America on the radiography of the chest. It is the first real attempt to combine the clinical with the radiological side of diagnosis, at any rate in a pleasantly readable form. I have referred to one book that in my opinion no radiologist ought to miss the opportunity of reading; I refer to "Radium, X-Rays and the Living Cell," by Russ and Hector Colwell. So orderly is the sequence of this, the second edition, I think, that reading it is a pleasure. Surely the biological aspect of irradiation therapy is the one possible avenue by which we shall find the light we are seeking. In spite of all the amount of careful research and the immensity of trouble the authors must have taken in the preparation of the book, they very modestly wind up with a statement which seems well worth recording. They write as follows: "The way towards any working theory of action must be gained by accurate observation; with such a basis theory will predict how further facts may be ascertained. It may be realised that we are only at the threshold of the subject; ever-increasing coöperation between the chemist, the clinician, the pathologist, the physicist, and the physiologist will help to solve the problems involved in considering the mode of action of the rays. In radiology applied to biological problems there is a double difficulty, for the intensity of the irradiation, be it X ray or radium, is a quantity which under experimental conditions presents very considerable difficulties in its accuracy of measurement, and the animal itself represents a complex which refuses to be reduced to simple terms."

HIGH-VOLTAGE THERAPY.

It is difficult to discuss at the present time the great advance that would appear to have been made by the researches of Wintz and his associates at the Erlangen School. The method of high-voltage therapy was introduced into this country by Reginald Morton. So impressed was he by what he had seen that in order to devote himself to this work he was courageous enough to throw up all his other work—all honour to him. It is difficult, however, to appreciate how far we are sailing on the right tack. It seems to me, and this was the impression conveyed not only to myself but to many others during a most interesting discussion on the subject during the last session, that by this method we have approached a good deal nearer to precision as regards skin dosage at any rate, but that we are at the present time engaged in a strategic retreat in order to improve our position in the future. We are, I suggest, very properly doing some careful reconnoitring with a view to the question as to whether all cases for which radiation therapy is required are of necessity those for which rays of short wave-length are always indicated. Before very long I would submit the profession in general will require an answer, and an answer in no uncertain terms, on questions such as the following:—

1. Has high-voltage therapy given better or more promising results than have been obtained by the older methods?
2. Has high-voltage therapy given better results in the class of case that has hitherto baffled the ordinary methods or the technique of such places as the Radium Institute, for example?
3. Has high-voltage therapy done more to prolong life (quite apart from any question of "cure"—a word which, for the present, we have very wisely left out of our vocabulary)? I do not refer to such incidental cases as are familiar to all of us who have been engaged for a number of years in radiation therapy. From the very earliest days, radiologists can point to many cases of apparently wonderful arrest of new growth,

4. Has high-voltage therapy succeeded in arresting the progress of recurrent carcinoma of the breast in the fat and plethoric woman?

I am not going to attempt an answer, but I feel sure that you will agree that, for the next few years at any rate, no session of our own Section ought to pass without at least one evening being spent in a discussion upon this most important subject.

DOSAGE.

The term "lethal" dose I think ought to be dropped, except in the limited sense of "inhibiting growth," and, incidentally, the expression "stimulating" is misleading as having little or no ground in a scientific sense for its use as applied to radiation therapy. If one works upon the theory so well expounded by Dr. James Ewing (a précis of whose illuminating paper can be read in a recent number of the *Archives*) that the clinical results depend not only on the injurious effect to the tumour cells but also on the defensive action of the body and the tissues, the results may be more satisfactory and the possible harm to the patient less. By employing less than the so-called "killing" dose of Wintz and Geitz, repeated at intervals, most of the embryonic and lymphoid tumours react as well as with heavy dosage and without notable disturbance. If there are any who have not read the paper to which I have referred I think the conclusions are worth stating. They are as follows: (1) That no uniform dose can ever be established, each case requiring individual consideration; (2) that results will not improve with increase of dosage; (3) that deep therapy cannot safely proceed upon the direct killing of the cancer cell. I think the very instructive and fair résumé written by Knox in a recent number of the *British Medical Journal* ought to be studied by all of us.

THE BRITISH INSTITUTE OF RADIOLOGY.

Lastly, I would say a few words about the British Institute of Radiology, which we hope may in some way be linked up with the Royal Society of Medicine. You all know that the Institute has come into being by the absorption of the British Association for the Advancement of Radiology and Physiotherapy—a title as long as it was comprehensive. It forms the very keystone of the latter Society. Alas! the untimely death of Archibald Reid came at a very bad time for the Institute. There are two very distinct types of men. One, the type that goes full steam ahead and budgets later; the other, the type that budgets carefully and then slowly steams away. Reid was one of the former type, and to his infectious enthusiasm and optimism we owe the fact that the Institute is in being. Suitable premises on favourable terms have been secured at 32, Welbeck-street, and only more enthusiastic members and money are needed to give it a good send-off. Reid's dream, as he often said to me, was that the Institute should become a central information bureau on all matters affecting radiology, and that it should form a nucleus for a world-wide organisation, and should be the meeting place for all our international colleagues when they visit England.

Should there be any present who are not already associated with it, I am sure I am voicing the wish of the Council in giving them a very cordial invitation. Not only do we want radiologists and our good colleagues in other branches of physical medicine, but we need, above all, the help and counsel of the physician and the surgeon. It is hoped in time to have a good reference library, but, above everything, a complete record in the shape of lantern slides of the whole of the normal and abnormal body. New blood, especially young new blood, is vital. Are all the younger radiologists so busy making their fortunes that they have no time to give a hand by sitting on committees and making the Institute the success it ought to be? If for nothing else than as a memorial to our old friend and colleague, Archibald Reid, it is worth doing.

Dr. John Muir, to whose enthusiastic help as secretary to the Institute we owe it that the Council has been able to proceed, will, I know, be only too pleased to give any further information to those interested, or to discuss the financial position with any benevolent millionaire.

HOPES FOR THE FUTURE.

It is pleasant to ponder over our beginnings and to have the feeling that we are slowly but surely advancing. "All that is human must retrograde if it does not advance," as Gibbon wrote in "The Decline and Fall," and I am confident that we are not doing the former. We are, it is true, behind our American friends in the general adoption of team-work of the highest quality, I mean team-work as has produced such wonderful results at the Mayo Clinic. It is still a matter of surprise, if not of pain, to know that in this country it is not infrequently considered satisfactory to have merely a technician (even though he be well trained in his art) at the head of a scientific laboratory. It seems to me an equally wrong and retrograde movement that is taking place in many of our Poor-law infirmaries, even in those which pride themselves upon being "up to date" in other respects. Good X ray apparatus is provided at the cost of the ratepayer, but it would seem to be equally important that such apparatus should be used to the best possible advantage. This can only be the case if a trained and qualified medical man is at the head of the department. I think the time has come when from this place or from another our views should be laid before the Ministry of Health and the various boards of guardians. Our American and continental friends are amused that such a condition of things can be. Signs, however, that better counsel is prevailing is seen in the London Clinic, in which, at any rate from the only standpoint from which we are able to judge, there is nothing left to be desired. I mention the above only to emphasise that, in my opinion at any rate, we have not yet attained to the fullness of our growth. Let us make no mistake. Until the time arrives when by our training and our general knowledge we become indispensable to the cause of diagnosis, we cannot feel that the battle has been won. The time for watertight compartments or for universal specialism in medicine or surgery is a thing of the past. I always like to think of the consulting physician or surgeon in the position of a judge, and ourselves and other people engaged in arriving at a diagnosis as counsel. The judge collects all the necessary evidence, bears upon it the weight of his own knowledge and experience, and, finally, pronounces judgment. In such a perfection of medical life the radiologist has a very great deal of essential evidence to offer, and in this way, and in no other, will he come into his own.

DONATIONS AND BEQUESTS.—Mrs. Greenup, of Knutsford, left £1000 to the Knutsford War Memorial Hospital "as a mark of appreciation of the kindness and attention which she received when she was an inmate of the hospital."—The Royal Infirmary, Liverpool, through the medium of the Joint Council of the Order of St. John and the British Red Cross Society, has received a cheque for £1500 from the "Dennis Bayley Fund." A bed will be endowed primarily for the use of ex-Service men as a memorial of the sacrifices made by workers of the Order of St. John and the British Red Cross Society during the war and in commemoration of the work of the Fund for the Transport of Sick and Wounded, 1915-18.—Mr. E. F. Callisher, of Birkenhead, has sent a cheque for £2000 to the chairman of the Liverpool Babies' Hospital (Miss Margaret Beavan).—The late Mr. Meyer Elias Sassoon, of Bombay and London, left by will £5000 to King Edward's Hospital Fund for London.—The executors of the late Mr. J. G. Litton, chartered accountant, Manchester, have given a legacy of £1000 to the Christie Hospital (Cancer Pavilion and Home), Manchester.—The Earl of Ancaster has given £1000 towards £12,000 required for the enlargement of the Stamford and Rutland Infirmary.—Mr. Walter Wood, Worcester, left £2000 to the Royal Albert Orphanage, Worcester.

THE BABINSKI OR EXTENSOR FORM OF PLANTAR RESPONSE IN TOXIC STATES

APART FROM ORGANIC DISEASE OF THE PYRAMIDAL TRACT SYSTEM.

By T. R. ELLIOTT, M.D. CAMB., F.R.C.P. LOND.,

PROFESSOR OF MEDICINE, UNIVERSITY OF LONDON;
PHYSICIAN AND DIRECTOR OF MEDICAL UNIT,
UNIVERSITY COLLEGE HOSPITAL;

AND

F. M. R. WALSHE, M.D., D.Sc. LOND.,

F.R.C.P. LOND.,

PHYSICIAN IN CHARGE OF NEUROLOGICAL DEPARTMENT,
UNIVERSITY COLLEGE HOSPITAL.

THE extensor plantar reflex, if present over any period of time in other than infants, is generally accepted as certain proof of an organic lesion implicating the pyramidal tract. There are, however, some exceptions to this main rule of which one at least is familiar to physicians. Patients with frequently recurring epileptiform fits, either from ordinary epilepsy or from uræmia, may show a strong extensor response during and for a day or two after the period of fits; and yet they recover without the development of any organic lesion. It is less well known, though mentioned in respect of one case of acute yellow atrophy of the liver by Sir Humphry Rolleston,¹ and illustrated subsequently by several cases of severe infective jaundice reported by Sir William Willcox, that cases of severe hepatic insufficiency may show an extensor response for the day or two preceding death.

Insomuch as the plantar response is often relied upon in the examination of comatose patients as a means for distinguishing whether the coma is due to organic lesions, such as a cerebral hæmorrhage, or to some other and toxic cause, it is of considerable clinical importance to know precisely in what toxic states the extensor response may be found. Our experience has shown that there are many such states; but the accumulation of evidence from one hospital is slow. This preliminary paper is therefore written in the hope that other physicians may be inclined to examine the question in the various toxic states that chance to come under their observation, and that so a body of information may be collected from which it will be possible to deduce the general principles that govern the form of the Babinski reflex.

The chief text-books on neurology do not refer to the phenomenon in toxic states; the reason, perhaps, being that the cases of coma in which an extensor response may occur are those which come under the care of the general physician rather than of the neurologist, and the former, seeing his diagnosis fairly clear on other grounds, does not trouble to investigate the plantar reflex which would have been tested as a matter of routine by the neurologist. Thus Oppenheimer gives only one exception to the rule that the extensor response indicates an organic lesion—namely, that in idiopathic epilepsy the extensor reflex may occur during and for a short time after a fit, whereas it is never found in hysterical fits. Babinski himself, in the 1913 edition of "Travaux Scientifiques," does not discuss the possible occurrence in other than organic lesions of the extensor reflex which he first described in 1893.

Some observations in a physiological paper by Kleitman² are of particular interest in this respect, for he showed that an extensor response was present in healthy young men during the very deep sleep that followed deliberate deprivation of sleep for a period of 40 up to 110 hours. The response became flexor as the sole was repeatedly stimulated, and at

the same time the depth of the sleep was diminished. These results confirm the reports of some previous observers, and make it certain that an extensor response can appear in tired, but otherwise healthy adults during deep sleep, and be reversed on waking. It must therefore be borne in mind, when considering possible toxic causes of an extensor response, that the latter may sometimes be produced during deep sleep. But this caution does not greatly affect the practical clinical observations of this paper—namely, that independently of the depth of the coma an extensor response may occur in some toxic states and not in others.

In the instances given from our experience, only clear and unequivocal extensor responses are accepted; and they were obtained in the customary way by stroking or scratching the outer part of the sole of the foot, other possible fields of stimulation, such as the front of the leg, not being used.

Diseases of the Liver.

The toxic state of severe hepatic insufficiency, sometimes spoken of as "cholæmia," is associated with an extensor response; and in our opinion this sign should be used as a definite test for the onset of cholæmia in cases of liver disease. "Cholæmia," despite the name, has nothing to do with jaundice, and it may or may not be associated with the latter. The condition may arise in any diseased state that has seriously impaired the general functions of the liver, apart from that concerned with the bile pigments. It does not appear to be related to a suppression of urea formation or of sugar output from glycogen. The damage to the liver may be acute, as in severe infective jaundice or acute atrophy; or it may be chronic, as in cirrhosis or extensive carcinomatous deposits, when it is particularly liable to appear after any further sudden disturbance of the patient as by hæmorrhage or surgical operation. It is recognised by the mental changes of mild delirium or drowsiness, associated with a double extensor response; and it soon deepens into complete coma which ends in death.

Sir William Willcox¹² has referred to the mistaken etymology of the term "cholæmia," pointing out that bile may be present in great excess in the blood and yet not cause these toxic symptoms. He does not describe any case of cholæmia without jaundice; but he insists that the depth of the jaundice is not related to the intensity of the toxic features, and suggests that the term "icterus gravis" should be used for the toxic form. This suggestion, however, does not avoid the difficulty because the state can arise without any icterus at all. It seems better, in our present ignorance of the biochemical disturbances involved, to continue to use the word cholæmia for the clinical state, just as uræmia is still employed for the analogous toxic picture in acute or chronic renal disease though excess of urea in the blood is not the poison directly in action.

The following three cases illustrate the development of toxic features with an extensor response as the result of fresh disturbances in patients with chronic hepatic insufficiency, while the fourth shows the condition arising spontaneously and with slower progress.

CASE 1.—Man, aged 60, admitted to hospital with great ascites. History of syphilis and of chronic alcoholism. Wassermann negative. Plantars flexor. No jaundice. During the next 18 months the abdomen was repeatedly tapped, a total of over 30 gallons of fluid being removed. The ascites then lessened and a free collateral portal circulation became established. A year later he had a severe hæmatemesis from oesophageal varices, and was admitted to hospital semi-comatose, but irritable so that he reacted strongly to cutaneous stimulation. Double extensor response. Blood contained 0.11 per cent. sugar and 0.04 per cent. urea, the liver, therefore, not being entirely out of action. Coma deepened and knee-jerks vanished, while plantar response remained extensor for three days up to death. At necropsy the liver was very small, showing extensive cirrhosis and some portal thrombosis. Cerebral vessels

were normal. The sudden cholæmia had probably been caused by the large hæmorrhage.

CASE 2.—Woman, aged 46, who a year previously had had an attack of "catarrhal jaundice" for four months. She recovered for work, but a trace of jaundice persisted. Admitted to hospital with faint jaundice and advanced ascites from portal obstruction. Not wasted and no fever. Plantars flexor. Wassermann not tested. The abdomen was tapped and the fluid continued to leak through the opening left by the trocar. Next day the patient became drowsy, and when examined the day following she was in mild coma with increased knee-jerks and a double extensor response. Temperature 97° F. Blood-urea was then 0.017 per cent., a low figure suggesting liver failure. The patient died next day. Necropsy: Liver very atrophic; brain normal; semi-purulent peritoneal fluid in the pelvis, perhaps a result of the paracentesis abdominis and subsequent leakage.

CASE 3.—Barwoman, aged 35, addicted to spirit drinking. Four months' history of ascites, cedema, and very slight jaundice. Admitted to hospital with features of portal obstruction and with slight pyrexia, about 99° to 100° F. Jaundice very slight. Wassermann negative. Plantars flexor. No improvement in ascites though abdomen was twice tapped. Eventually the spleen, weight 9 oz., was removed in the hope of lessening the blood-flow through the portal system. Nine days after the operation the patient became excited and noisy and was mentally confused. Heroin gr. 1/10 given twice. Next day lethargic, with double extensor response. Died the following day. Liver extremely fibrosed and rather small. No macroscopic lesions in brain. A deep abscess at the site of splenectomy, which had perhaps caused the development of final liver insufficiency.

CASE 4.—Woman, aged 55, neither alcoholic nor syphilitic. Six years previous to death she had an attack of jaundice with pain, diagnosed in hospital as probably due to gall-stones. The jaundice never quite vanished, but there was no loss of flesh. Three weeks before death ascites became obvious, and a fortnight later the patient's mentality became slow and stupid. Plantars both flexor. Jaundice moderate. Two days before death coma supervened with deep respirations, and an extensor response, very definite on the right but equivocal on the left. Blood-urea 0.03 per cent., and blood-sugar 0.128 per cent. Liver cirrhotic and atrophic, weight 30 oz. Brain normal.

In contrast to these cases we have noted others, such as a protracted obstructive jaundice for nine months from cancer of the common duct without other liver disease, or a huge primary carcinoma of the liver growing for several months without jaundice, in which the patients sank quietly and slowly to death without acute mental changes and without an extensor response even in the last hours of life, that is, without cholæmia. In various forms of acute hepatitis and also in rapid destruction of the liver by known toxic substances cholæmia can occur. Such instances usually show an associated jaundice. Willcox (loc. cit., p. 65) described three fatal cases of this type during an outbreak in Mesopotamia of epidemic catarrhal jaundice; all these patients became irritable or maniacal, then comatose, and showed extensor responses in the last 24 or 48 hours of life.

We are not aware of any observations upon the plantar reflex in similar cases of spirochætal jaundice, but the difficulty arises in all these infectious maladies of excluding a possible invasion of the central nervous system by the actual infecting agent, which might thus produce mental changes and an extensor response directly and without reference to liver failure. The same confusion occurs in the interpretation of an extensor response in salvarsan poisoning with jaundice and liver destruction.

In the various reports published on trinitrotoluene poisoning with liver degeneration and jaundice mention is made of death preceded by convulsions or coma; the plantar reflexes are not discussed except by Willcox (loc. cit., p. 30), who refers to the occurrence of an extensor response, though he does not quote any actual cases. Eclampsia is a toxic state in which there is often serious destruction of the liver, and there may be slight jaundice. Fits are frequent; the patient may become delirious, comatose, and then

die. The obstetrical text-books do not refer to the state of the plantar reflex, though it is obvious that its character might be of importance in distinguishing eclampsia from other complicating diseases. Our own impression was that eclampsia did not lead to an extensor response, for in the first instance in which the latter was seen by us there was evidence of lethargic encephalitis complicating the illness of the confinement. Recently, however, by the kindness of Dr. H. R. Spencer we have seen one case of simple eclampsia with double extensor response. The patient was admitted with recurrent severe fits, the first of which had been followed by unconsciousness. She was not jaundiced. Next day when labour was in progress and the fits had ceased, the patient being mentally a little confused but not in the least comatose, the plantar reflexes were tested and found both to be extensor. Eight hours later they were both flexor. The patient made a straightforward recovery. It is therefore certain that a double extensor response can occur in the eclamptic state. In this instance we assume that it was a phenomenon associated with the status epilepticus, just as it may be seen in uræmia if fits are occurring. We have no evidence as to whether it may occur in the eclamptic state of coma without fits in which there is jaundice and liver destruction, thus corresponding more closely to cholæmia. In ordinary eclampsia an extensor response is rare.

Delayed chloroform poisoning is a toxic state, in which there is mild delirium, then coma, and usually death. A double extensor response is generally present. The liver shows fatty degeneration, and it is customary in pathology to ascribe death to a toxic action of the chloroform on the liver. If the analysis is true, this state is then very similar to that of cholæmia. Ether, also, may perhaps cause the same clinical series of events, as in a case which we quote by the courtesy of Dr. Batty Shaw.

The patient, 41 years old, had recently had hæmatemesis from a gastric ulcer and was moderately blanched; pulse, 104. Gastro-enterostomy was performed under ether, with a small dose of scopolamine and morphia beforehand. Next day she became delirious and on the following day had a double extensor response, dying soon afterwards. She was not jaundiced. The liver was large and the seat of acute fatty infiltration and degeneration.

Throughout the series of diseases so far discussed there has run the common factor of liver damage with a consequent toxic influence on the brain leading to coma and an extensor response. This relationship naturally brings into thought that rare malady, hepato-lenticular degeneration or Wilson's disease, in which the liver is fibrosed and there are manifest lesions in the brain. But the comparison throws no light on the question, for a leading feature of that disease is the absence of extensor plantar responses during the ordinary progress of the illness. The patients are not jaundiced; it is uncertain whether their death may ever be preceded by a final cholæmic state, for the published cases do not state the character of the plantar reflex in the last days of life. In one case observed by one of us, and recorded elsewhere,⁴ the plantar responses were still flexor within a few hours of death.

Other Intrinsic Toxic States.

The condition of cholæmia from liver damage has been discussed at length, and the suggestion made that it can be identified by the extensor response. Diabetic coma is as deep as that of cholæmia, but it is rarely preceded by the restlessness and light delirium that are associated with cholæmia and it is not accompanied by epileptiform fits. We have never found an extensor response in any case of diabetic coma, even after two days of coma and within an hour of death; and we have not discovered the record of anything but a flexor response in patients under the care of other physicians.

Hypoglycæmic coma produced by overdosage with insulin may be ushered in by fits. Emmons³

has recently described a case of coma, apparently without fits, in which both plantar responses were extensor. If this observation were proved to be generally true, the state of the plantar reflexes would be of great value in distinguishing between ordinary diabetic coma and that from hypoglycæmia. In the state of mental confusion and restlessness seen in relatively mild hypoglycæmia we have always found the plantar response to be flexor. Deeper coma we have not had any opportunity to study. In the only case of cyclic diarrhoea and vomiting that has come under our observation, a boy of 8 with repeated attacks associated with ketosis, restlessness, and great collapse, the plantars were flexor and the blood-sugar was not lowered.

An alkalosis of the blood was suggested by Heyd, Killian, and MacLean⁵ as the possible cause of drowsiness, coma, and death which developed in some of their patients after operations on the bile-passages. The plantar responses were not described, so that their clinical picture cannot be identified as that of cholæmia. There is no evidence at present as to whether an alkalæmia can produce an extensor response. The plantar reflexes were not described in the examples recently analysed by Ellis.² In a case recently seen by us, of adult tetany with vomiting for months and great collapse, where alkalæmia may have been associated with the tetany, but no actual analysis of the blood was made, the responses were flexor up to an hour before death. The vomiting in this case was not caused by pyloric obstruction, but may have been due to disease of the suprarenal glands.

The possibility of an extensor response occurring in acute uræmia is well known to physicians and it is unnecessary to quote illustrative cases. We wish to emphasise that we have seen it only in cases with epileptiform fits; that despite associated unconsciousness it has no sinister prognosis; and that the reflex may become flexor within a few hours after the fits have ceased. In cases, either of acute or chronic uræmia, that lapse into coma and die quietly without fits we have never seen an extensor response even in the hour or two before death. The extensor response of uræmia is therefore, so far as our observations go, not essentially related to the coma nor to the toxic state; it appears to be a phenomenon arising secondarily to the epileptiform fits, and presumably its pathology is the same as that of the extensor response in fits from idiopathic epilepsy.

Poisonous Drugs.

The action of chloroform in delayed poisoning has already been discussed. It has been stated by Bickel that in ordinary anaesthetisation an extensor response may be observed at the degree of anaesthesia which just precedes obliteration of all reflexes. This has not been generally confirmed. Some hypnotic drugs, when taken in excessive doses, can produce a coma, not necessarily fatal, during which a double extensor response may be very readily demonstrated. This is obviously a matter of importance in the differential diagnosis between coma from poisons administered and that arising from internal disease. One of us¹¹ many years ago described such an instance from sulphonal poisoning. The patient, a man of 21, had taken 15 grains of sulphonal nightly for a fortnight. He was brought into hospital drowsy and then became restless, with a double extensor response which led an experienced neurologist, who also saw the patient, to diagnose the condition as that of tuberculous meningitis. The response became flexor in the next 24 hours and the patient in a few days made a complete recovery.

With regard to veronal, we have no observations of our own. W. Cole¹ records a case with profound coma in which the plantars were flexor. The patient died in three days. Sir William Willcox has kindly informed us that he has seen extensor responses in veronal poisoning, though the cases have not been published. There is no clear evidence to indicate

whether the fatty degeneration of the liver described with veronal poisoning has any significance in this connexion. Opium poisoning has apparently not yet been observed to lead to an extensor response. Scopolamine is a drug of considerable interest in this respect. Our attention was drawn by Prof. A. J. Clark to a paper by Rosenfeld in 1921,¹⁰ which apparently followed an earlier one by Lenk.⁸ Rosenfeld concluded that subcutaneous injections of scopolamine, 0.5 to 1.0 mg., could be used to differentiate paralysis agitans and corpus striatum motor defects, in which the Babinski response remained flexor, from other nervous states in which the drug produced an extensor response. Rosenfeld made some erroneous statements, such as that an extensor response is never seen in terminal coma from bodily disease; but his statement that the drug may be used for a differential diagnosis is true, though not entirely in the sense indicated by him. Subcutaneous doses of 1/100 or 1/150 gr., which cause only slight drowsiness, do not change a flexor into an extensor response in a healthy subject, but they may do so in a patient with a minimal degree of pyramidal tract affection. The drug has, therefore, a very real value for clinical diagnosis in unmasking a doubtful or a hidden extensor response.

CASE 5.—Man, aged 51, with small cerebral tumour. A one-year history of transient attacks of motor aphasia with Jacksonian movements of right lower face and of tongue. After such an attack examination revealed slight clumsiness of movement in the right arm and hand and slight paresis of the right lower face. Both plantar responses flexor. No papilloedema. On two separate occasions a hypodermic injection of 1/150 gr. scopolamine was given. In each instance an unequivocal right extensor response was obtained within an hour, reverting to flexor a few hours later. Necropsy, after an unsuccessful exploration, revealed a small glioma at the foot of the left ascending frontal convolution.

Lethargic encephalitis may occasionally be accompanied by an extensor response, and in rare instances the latter may be found in post-encephalitic Parkinsonism. It is probable, therefore, that the pyramidal system is not absolutely free from involvement in this disease. We have observed several cases of the Parkinsonian syndrome where a full flexor plantar response was readily converted into an extensor response by gr. 1/100 of scopolamine given hypodermically; but our experience does not enable us to say that this change in the plantar response can be used to differentiate the post-encephalitic from the ordinary senile variety of paralysis agitans. Lemos,⁷ apparently without knowledge of the German writers, noted that scopolamine, when used in the treatment of the tremor and rigidity of the Parkinsonian syndrome in patients who have had lethargic encephalitis, can lead to the appearance of an extensor response; and he also suggested that the drug might be used to reveal a clinically latent involvement of the pyramidal system.

Coal-gas Poisoning.—In view of the ambiguous circumstances in which patients comatose from carbon-monoxide poisoning are often brought up for medical diagnosis and treatment, it is surprising that published observations on the plantar reflex are so rare. Wilson and Winkleman¹³ found the response flexor on first examination of two cases which ultimately died, but it does not appear that the reflex was tested again after the first observation. We found clear double extensor responses in each of the two cases that we have latterly had the opportunity to test in hospital.

CASE 6.—Man, age 49, who was found unconscious in his room at an hotel, the gas being turned full on and the disposition of the room suggesting deliberate preparation for suicide. Admitted to hospital at 9.45 A.M. unconscious. Carbon monoxide found in the blood. Temperature 101° F., pulse 120, respirations 48. Never regained consciousness. Temperature and respirations continued to rise and patient was in drenching sweats. Next morning temperature 103°, pulse 160, respirations 60. Deeply comatose; limbs rather rigid, but devoid of all involuntary movements. Knee-jerks normal; double extensor response. Died the

same afternoon. Brain slightly oedematous, no petechial hæmorrhages. Lungs deeply congested and showing inflammatory oedema.

CASE 7.—Man, age 18, found unconscious in his lodgings at 2 P.M. with gas-jet accidentally left open; was quite well the previous night. Admitted to hospital 4 P.M. Unconscious; slight cyanosis; profuse perspiration; temperature 100° F., pulse 124, respirations 44. Pupils reacting well, knee-jerks increased, double extensor response. Colour improved by oxygen, but no recovery of consciousness. Died next day, temperature rising to 103°, with pulse 140 and respirations 60. All organs showing intense venous congestion, brain otherwise normal. Lungs showed inflammatory oedema, together with small areas of broncho-pneumonia under the microscope and some purulent fluid in the bronchioles.

Both these cases were seen late and the carbon monoxide had largely been eliminated from the blood, but the brain had failed to recover from its prolonged anoxæmia and was meeting with further defective oxygenation of the blood from progressive broncho-pneumonia or inflammatory oedema of the lungs. The very severe features of pulmonary inflammation seen in each case, with rising temperature and respiratory rate, suggest the action of some unusual pulmonary irritant apart from the carbon monoxide in the illuminating gas. There is no knowledge of the time at which the plantars became extensor. It is therefore impossible to suggest how severe and of how long duration cerebral anoxæmia must be in order to change the plantar response to the extensor type. We have never yet seen an extensor reflex even in the most cyanotic and comatose cases of simple broncho-pneumonia or pneumonia. Nor have we seen it in cases of slow heart failure, when pulseless, semi-comatose and cyanosed from peripheral stasis and pulmonary obstruction.

It is a matter for regret that no observations were recorded on the plantar reflex in casualties during the war from phosgene gas-poisoning, when cyanosed and comatose. In lack of knowledge on this point in such analogous states or in the unconsciousness that follows ordinary drowning, the relationship of cerebral anoxæmia to the development of an extensor response cannot be analysed further, and we must be content to record the possibility of this form of the plantar response in coal-gas poisoning.

Summary.

1. An extensor plantar response characterises the toxic state of coma without epileptiform fits ("cholemia") that may arise when the metabolic functions of the liver are seriously impaired by acute or chronic diseases of that organ.
2. An extensor response does not occur in diabetic coma, nor in uræmia except when the latter is associated with epileptiform fits. It has been seen in eclampsia with fits.
3. Delayed chloroform poisoning, sulphonal poisoning, and coal-gas poisoning may all lead to the appearance of an extensor response in the absence of any organic lesion of the pyramidal tract.
4. Scopolamine will convert a flexor response into an extensor type in cases where the pyramidal tract system is only slightly affected, and the drug may therefore be used to unmask a latent or equivocal extensor reflex.

VENEREAL DISEASES IN MEN AND WOMEN.

A STUDY OF THE AGE-INCIDENCE.

By DOUGLAS WHITE, M.D. CAMB.

THROUGH the kind offices of Colonel L. W. Harrison, of the Ministry of Health, I have been able to go through the records of the V.D. treatment centre at one of the great London hospitals, in the hope of obtaining some reliable knowledge as to the age-incidence of syphilis and gonorrhoea among men and women at the present day. The result of this somewhat tedious piece of work is, I think, worth recording, since it seems to throw some light on a difficult problem.

Method of Investigation.

First, as to my method. I only dealt with those persons who attended the clinic since the card-index system was adopted. On these cards are recorded the answers to a series of questions on personal history; the cards contain no names, but numbers; the year of age is given with the probable or approximate date of infection; inquiry is made as to previous infections and their dates.

It therefore appeared to me that I might draw up two tables, the first showing the age at which the *present* infection was acquired, distinguishing between syphilis, gonorrhoea or chancroid, and double infection, also between married and single men; the second showing the age at which the *earliest recorded* infection was acquired, with the same distinctions. This proceeding I found practicable in about two-thirds of the male cases. Of the remaining third, a large proportion were diagnosed as having no venereal disease after bacteriological and serological examination. Of these, however, some had a dated history of former venereal ailment; such cases are recorded in the table giving ages of *first* infections but not in the table of *present* infections. A further proportion gave reliable histories as to *present* infections, but either denied previous infections, or, without denial, gave no history. Denials are here treated at their face value—however unreliable—and such *present* infection is also entered as a *first* infection. Where no denial but no former history is given they are recorded as *present* infections, but not as *first* infections. From this it will be clear that while the two records (men) of *first* and *present* infections consist largely of two records of the same persons, yet many persons are recorded in only one of the two. Hence, in my list of “*first* infections” there are 5782 cases recorded, but in my list of “*present* infections” only 5396.

The age of infection, recorded here, is not necessarily the age of the patient when treated. A man, for example, aged 54, suffering from *tubercles*, says he contracted syphilis 30 years ago. He goes down as *present* infection, syphilis, age 24. In such cases the memory of years is often surprisingly definite; but where round numbers are given it is hoped that inaccuracies will cancel out. Cases of *parasyphilis*, however, form only a small percentage. But in other cases also a difficulty arises as to the exact year to which the *present* infection should be credited—e.g., a case of secondary syphilis, acquired, say, seven months ago; man's age 25. I have assumed in all cases that such a man, when he comes for treatment, is midway between his declared age and the next higher—in this case 25½. If, therefore, his infection is over six months old, he goes down as 24, if less than six months, as 25. By this method the amount of error will be small, and a fair balance will be reached.

About 9000 cards of men were examined; no selection was made except to neglect those where there was either no V.D. or no history fixing the date of infection, or cases of congenital syphilis, which for this purpose are irrelevant. For the purpose of tabulation, widows and widowers have been treated

as single, which, indeed, they are as far as sex relationships are concerned. To have made a separate category would have increased the complexity. Children younger than those here recorded are not usually dealt with in this department of the hospital, hence they do not appear in the figures.

In the case of female patients greater difficulty was encountered, inasmuch as inquiry from women patients is in any case a more delicate business; moreover, a large proportion, specially of the married women, are genuinely ignorant of the date of their infection; hence, only 1720 women patients are recorded out of about 4000, simply owing to the lack of reasonably reliable information. Among the women, also, it was found impossible to make out any table of *first* or previous infections; hence, the records of women (two graphs) give the age of “*present*” infection only, which is comparable to that giving the age of “*present* infection” for the men.

Results.

Passing on now to results. The actual figures of my tables are reproduced in the form of “graphs.” Two graphs are given of each table—the one divided into areas of syphilis, gonorrhoea, and mixed infections, the other into areas of married and single at each age. Although the outline of the graphic tables has at certain points a somewhat jagged appearance, it is surprisingly regular in its general form, especially when the small age-intervals are considered (one year) which render some error inevitable; the raggedness, of course, becomes greater as the numbers get smaller. Each curve, however, tells its own story quite simply and decisively. Each curve also is markedly skew, rising sharply from the start (in the case of males) at 14 to a summit between 21 and 22 for “*first* infections,” and at 24 for “*present* infections”; after this it drops nearly, but not quite, as sharply as it rose, to about 33, after which it tails off all the way to 60. The curve of the women, starting at 11, reaches a summit between 21 and 22 (“*present* infections”—two years earlier than the men) tailing off in a similar manner to the men. The female graph is given on a larger scale so as to be roughly comparable with the male curves.

Attention may be drawn to certain points. The age-incidence of syphilis seems to show no significant difference from that of gonorrhoea on any of the curves, but the total proportion of syphilis to gonorrhoea is greater in *present* than in *first* infections, being in the former about 1:2, in the latter slightly over 1:3. In the case of women it is still greater, being about 1:1.2. Probably a larger number of women fail to present themselves for gonorrhoea, being ignorant of their condition, than for syphilis, where the secondary symptoms, if not the primary, demand attention. Mixed infections, also, are seen to be relatively commoner in the women than in the men, and in *first* infections of men than in the later.

Incidence in Single and Married.

Turning now to the incidence of V.D. in single and married men, we find that in our table of “*present* infections” three-fourths of the whole occur in single men, one-fourth in married men. For these men the maximum (*present* infection) is reached at age 24. At this age the infections of married men account for one-seventh of the whole, while in the population of London, the married men of that age are one-third of the whole. For married men the maximum infection occurs at age 28, being at that age half of the single incidence; the numbers of single and married men in the community having become equal at age 26-27. At age 35 the disease incidence as between married and single has become equal, at which age the married men in London outnumber the unmarried by 4:1. After this age the married incidence preponderates, though disease is rapidly decreasing in absolute quantity.

Among the women the case is very different. With them the married incidence of disease is 25 per cent.

greater than the unmarried. This affords a striking contrast to the male incidence, even when we allow for the fact that this hospital is not much utilised by women of the prostitute class. The excess of married women infected begins at the age of 22, which year also shows the highest total figure. This marital preponderance is the more striking, since at the age of 22 only one-fourth of the women of London are married. And after the age of 22 the married preponderance increases steadily. It has been pointed out to me that this excess of married women may be partly artificial, owing to the fact that married women can be and often are brought to treatment by methods of persuasion which are not available for the unmarried. On inquiry I find that since the opening of the department in 1921 such persuasion has been increasingly cultivated. In the most recent figures (1923-24) the married excess is more like 50 per cent. than 25 per cent. In the earlier days the pressure was less effective; yet from the first there has always been an excess of married women.

On the whole I am inclined to think that a large proportion of the 25 per cent. excess may be artificial. But if the whole of the excess were artificial, the general argument would not be affected. Single men are affected three times as much as married; married

and single women equally. If, however, the married excess, as a whole, were entirely discounted, then the excess of married women over single, for particular ages, would begin at age 24 instead of age 22 (as given in text above). Incidentally, it may be said that while the formal distinction between married and unmarried is sharp, the ethical distinction is blurred, a considerable number of the women stating that they were infected by their fiancés, and many of them still desiring to marry the same man.

As regards the graphs, it remains to say that they are so scaled as to be roughly comparable with each other. If the other curves were scaled in exact proportion to that of "men, present infection," then the curve of "men, first infection" would show at age 22 an apex not of 513 but of 478—60 higher than the apex of "present infection." Similarly, if the number of women's infections were multiplied so as to equal the men's, their graph would show a maximum at age 22 of 505—87 higher than the apex of the corresponding men's curve.

It should also be noted that the apex of "first infections" of men stands in the graph at age 22, while in that of "present infections" (i.e., taking them as they come to hospital) the apex stands at 24. This means that when we compare "first infections" with "present infections," the curve (as might be expected) gets pushed back and heaped up at the earlier age. In my judgment, if the men had confessed more truly to earlier infections, the "first infection" curve-apex would have been pushed back further still, and with a higher apex, at the age of 21 or even 20. The women's graph, being of "present infection," is only comparable with the "present infection" curve of men. The women's apex occurs

at age 22, the men's at 24. If a women's curve of "first infections" had been available, it would no doubt have been correspondingly pushed back and heightened, with an apex at about age 19.

Social Significance of these Statistics.

What, then, is the social significance of these statistics? Two points in particular appeal to me. First, it is evident that habits of sexual promiscuity

are formed in a very early period of adult life, and that the mental outlook, which gives rise to these habits, originates during adolescence, or even earlier. We may do a large amount for the abatement of venereal diseases by treatment and, to some extent perhaps, by artificial prevention, but the root of the matter lies in the outlook which is engrafted at the home and in the school. I am persuaded that much can be done to remedy this fundamental evil; and it is equally clear that nothing serious is now being done, save by the individual efforts of a relatively few parents and teachers, many of whom are ill-equipped for their task. The matter demands the joint attention of the Board of Education and the Ministry of Health. Secondly, the figures may serve to throw a partial and indirect light on the question as to what effect, if any, among our workaday classes, marriage has upon the incidence of V.D. The significance of the distribution of V.D. between single and married persons depends on the proportion of single and married persons, at each age, in the community from which they come. For this latter ratio the 1921 census figures are published for the administrative County of London. This is, indeed, rather a wide area for our purpose, but, as far as proportions of

married and single are concerned, it does not materially differ from the proportions which prevail in the five boroughs adjacent to the hospital in question.

Taking, then, the proportions of married to single men in London at different ages and comparing them with the proportions found in this V.D. record for married and single men at similar ages, the following tentative conclusions are reached. In men of all ages there is a smaller proportion of V.D. among the married than among the unmarried. But the extent of this favourable effect of marriage is not constant; its effect is at its best at ages from 30-35, when married men are less subject to

V.D. than single men in the ratio of 1 to 4. From this age up to 45 the favourable effect seems to diminish towards a ratio of 1 to 3; but here our numbers of men affected are too small to make the increased ratio other than conjectural. As we go backwards, however, from age 30, and more particularly from age 25, we find that the liability to V.D. of married men of the younger ages rises constantly, so that married men of a younger age than 30 appear to indulge in extramarital relations more frequently in proportion as they marry at an earlier age. [It is suggested to me that this apparently high liability of younger married men to V.D. may be due to a recrudescence of disease contracted before marriage, the recurrence being less likely after a longer lapse of time. I do not think this an adequate explanation of the statistics. If it were, it would only be another ground for the postponement of many early marriages.] Thus, according to my figures, if we take the liability of single men at each age to be represented by 100, that of married men from ages 19-30 is successively represented by 76, 53, 41, 42, 36, 33, 30, 27, 26, 31, 27, 24. Our figures, of course, at the earliest ages of marriage are small, but I think that the results as a whole are significant. If they are, they indicate that early marriages, before, say, the age of 25 for men, are relatively unsatisfactory as regards marital faithfulness, and probably also as regards happiness.

Except in the last-mentioned respect, the position of the women, again, is very different. While married men of all ages are less liable to V.D. than unmarried, married women at all ages are more liable to V.D. than unmarried women of the same ages. So far as they go, our figures indicate that, in proportion to the populace, married women of 27 years and over are about three times as liable to V.D. as unmarried women of the same ages; married women of 25 and 26 twice as liable; below 25 the married liability increases till at age 20 it is five times as great as for single women, and this excessive liability increases rapidly as the age decreases, till at age 17 the excess is enormous. If the 25 per cent. preponderance of married over single women, in this V.D. analysis, be discounted as artificial (as suggested above), still the excess liability to disease for married women of each age-group would by no means disappear, though it would be reduced by about 20 per cent. Married women at all ages would still be more liable to V.D. than unmarried women of the same ages, and very greatly so below 25. This state of affairs has its obvious explanation in the fact that wives are with great frequency infected by their husbands after marriage; the great excess in the first quinquennium of marriage (15-19) is no doubt largely due to infection at or before marriage by their husbands or by other men.

Effect of Early Marriage.

The picture, thus analysed, is a very different one from that of the men; it is only similar, in that early marriages in women, say, before the age of 22, seem to make very definitely for venereal disease. Whether these facts—if, indeed, they be generally true, as well as in the present survey—have been previously pointed out, I do not know, but they are worthy of meditation.

At present it is the custom to extol early marriages as preventive of venereal disease; it is probable that this opinion may have to be revised. The movement towards later marriages has been constantly growing over many years, though it received a slight and temporary check during and after the war. Economic prudence, often condemned as selfish, is also related to an increasing sense of responsibility; even if it were not so, educational progress, with the heightened sensibility which it engenders, tends to discount the success of early marriages; mental development goes on longer, and early affinities become less stable. Thus the tendency towards later marriages, though not free from evils, is both natural and beneficial; a general return to earlier marriage, if it were possible, would lead to less happiness and more disease. The opposite opinion, however, has to-day become not only

popular, but almost conventional. It has grown up during the last 20 years, in neglect of the weighty words of Havelock Ellis: "If all men married quite young, not only would the remedy be worse than the disease, but it would not cure the disease."

In conclusion, if I have generalised too widely on a slender basis, I do not forget that my figures represent only a local and limited experience of a hospital population. Yet it is hardly likely that other urban hospital populations would show very widely different results, and the mortality records of syphilis do not show that V.D. is less common in the upper, non-hospital, classes than among the hospital population. I can only hope that this tentative inquiry may lead to a more general survey, and towards the adoption of far-sighted educational measures.

INTUSSUSCEPTION.

A SERIES OF TWENTY CONSECUTIVE CASES.

By GEORGE M. GRAY, M.B., CH.B. ABERD.,
LATE RESIDENT MEDICAL SUPERINTENDENT, HOSPITAL FOR SICK
CHILDREN, GREAT ORMOND-STREET.

THERE is no disease of childhood which demands from the general practitioner earlier recognition than intussusception, and so the successful treatment of this condition will always be, to a great degree, a matter of fortune, in that the earlier a case is operated on after the onset of symptoms the greater is the chance of recovery. There are, however, a few points in the treatment which have considerable bearing on the question of success and will be dealt with here.

A tabulated list of the cases is given below.

Individual Cases.

The points of interest in individual cases are as follows:—

CASE 3.—This case had two days' history of attacks of pain, followed by vomiting and by blood-stained stools. The intussusception was not very difficult to reduce, except in the last 2 inches. It was of definite ileo-cæcal type, with dimpling of cæcum at the point of origin. No marked oedema of ileo-cæcal valve.

CASE 4.—Here the child passed blood after an attack of pain, before vomiting. The first vomit occurred on reaching hospital.

CASE 5.—Duration 24 hours. No definite history of vomiting, and only one blood-stained stool. The intussusception was ileo-cæcal in type and difficult to reduce, with a definite mesentery to ascending colon.

CASE 6.—Although of two days' duration the intussusception was very easily reduced and of ileo-ileo-cæcal type, with marked oedema of the ileal part.

CASE 9.—Had a definite previous history of gastro-enteritis.

CASE 10.—This intussusception had a very short origin from the ileum, and in the ileo-cæcal angle a small gland or cyst was found, which may have acted as a foreign body starting the intussusception, but this is unlikely, as the origin was distinctly proximal to it.

CASE 11.—This was an interesting case, as a definite Meckel's diverticulum, about 3 inches in length, was seen, about 2 feet from the ileo-cæcal junction, and in no way connected with the intussusception. Previous history of some gastro-enteritis.

CASE 12.—This case had a definite three days' history and was very collapsed. Vomiting had commenced immediately after a feed, and the child passed only two stools after the onset of symptoms, one mixed with blood, the second of pure blood. The intussusception was palpable as an elongated tumour in the umbilical region. At operation the tumour extended to the splenic flexure and was fairly easily reduced. It had begun a few inches proximal to the ileo-cæcal valve, and this ileal portion was very congested and more difficult to reduce. There was the usual oedematous dimple at the point of origin.

CASE 13.—Is of interest, as here we had a definite double intussusception, a primary ileal (enteric) about 1 foot in length extending to the ileo-cæcal valve, and a secondary one, a pure ileo-cæcal intussusception, extending to descend-

ing colon. The apex was not palpable per rectum, but a mass could be made out higher up. Fairly easily reduced, and the ascending colon found to be very mobile.

CASE 14.—In this case we had no history of vomiting, but had five blood-stained stools in six hours.

CASE 17.—This child came in very collapsed and was infused before operation, as it was considered to be her only chance. The abdomen was moderately distended. The intussusception was of the ileo-cæcal type, extending to below the splenic flexure, and was very easily reduced considering the duration of symptoms. The bowel was not gangrenous and only acutely congested. The ascending colon was *extremely mobile*, thus lessening the tendency to strangulation. The child was almost pulseless during the entire operation, and was kept alive after operation for two days with saline and glucose transfusions, but never really rallied.

CASE 18.—Here the child had a seven days' history, and the abdomen was so distended that no tumour could be palpated. This child was also in a very collapsed state when admitted. At operation an ileo-cæcal intussusception was found extending to the descending colon and was easily reduced, there being considerable oedema of the caput cæci. This was easily the most distended bowel we had seen, and as the child was not in good condition, immediate closure of the abdomen was attempted without inserting a trocar into the distended bowel; considerable pressure was necessary in getting the small bowel back into the abdomen, and the ileum perforated at its mesenteric attachment, a few inches above the cæcum. Some contents escaped, and the child was very weak when removed from the table and died soon afterwards. Whether it would have lived if the tear had not occurred is very problematic, but in future we shall use a trocar. This child had also a very mobile cæcum and ascending colon, and death would have occurred from toxic absorption from the bowel before ever strangulation or gangrene set in.

CASE 19.—This was our most interesting case in that it was a chronic intussusception with a two weeks' history as follows: "Sudden attacks of acute pain in lower abdomen and child vomited during the attacks. Child also had so-called diarrhoea for two weeks; motions dark, slimy, and offensive; no bright blood in motions. Twelve hours before admission passed bright red blood, about $\frac{1}{2}$ pint, and has passed more since." Tumour palpable in left hypochondrium. At operation an intussusception was found reaching to splenic flexure which was easily reduced. Child made an uninterrupted recovery. The cæcum and ascending colon were very mobile.

CASE 20.—The interest in this case is that it was a small tight ileal intussusception beginning in the ileum 10 inches above and extending only to the valve. Some difficulty in reduction; child also passed blood before it vomited.

General Remarks.

In the above series of cases the sex-incidence was 15 cases male, 5 female, which is about the usual proportion,¹ although no explanation of this can be given. All cases except three were under 1 year; three 4 months or under; nine between 4 and 8 months; five between 8 and 12 months, and three over 1 year, the eldest being 3 years. Most of the cases occurred in previously healthy children, which is the usual observation; in only two was a previous history of gastro-enteritis elicited. Of the ascertained cases nine were fed on the breast alone, five had been brought up on the bottle, and four had begun on the breast. These figures strengthen the belief that it is the strong, breast-fed, and presumably healthy baby who is most prone to intussusception.

The *symptoms* of intussusception are pain, vomiting, passage of blood, and presence of an abdominal tumour, and appear in the above order. Pain is always severe, the child crying out and drawing its legs up. Vomiting varies much in intussusception. It is usually persistent, but there may be only one vomit after the first screaming attack, and then no more; in no case was stercoraceous vomiting seen. Neither the frequency nor the violence of the vomiting gives any idea as to the site or tightness of the intussusception, as I have seen a high enteric intussusception with very little vomiting and a pure colic one with frequent vomiting. Sometimes vomiting is entirely absent, but this also does not help, as absence of vomiting was met with in two of the cases, one of which was a short, fairly tight ileo-cæcal intussuscep-

tion, and the other an ileo-cæcal, easily reduced one.

As "passing of blood" is a late symptom, cases should be diagnosed before its onset, but intussusception being relatively uncommon in practice, cases are usually diagnosed as colic until the passage of blood suggests intussusception. Blood per rectum was seen in all cases except one. Some authors say that it is neither a constant nor invariable occurrence.² In Case 19 no blood appeared until 12 hours before admission, but there was a history of diarrhoea for two weeks with dark, slimy, offensive motions; that is characteristic of chronic intussusception.³

Tumour.—This was palpable abdominally in all cases, but in some it was only distinctly made out when the child was under the anæsthetic. The size and position of the tumour varied greatly, but we found the "Signe de Dance" of confirmatory value, as in several cases there was a distinct emptiness of the right iliac region and also no gurgling over the cæcum was made out. This absence of gurgling is of doubtful value, but the converse is helpful in that if gurgling is elicited in the right iliac fossa, the chances of there being an intussusception present are slight. It must be remembered, especially if the child is under an anæsthetic and one is in an "intussusception" frame of mind, that the lower border of the right kidney is palpable in some children. In only five cases was the tumour palpable per rectum. In one case, in which there was doubt as to the abdominal tumour, a mobile tumour was easily made out bimanually, although the apex of the tumour did not reach to the rectal finger.

Varieties.

The varieties of intussusception present in the above 20 cases were ileo-ileo-cæcal, 10⁴; (so-called ileo-colic), ileo-cæcal, 7; ileal (enteric), 2; ileal ileo-cæcal, 1. Most writers give the ileo-cæcal as the most common form seen, but this was not found in this series. The true ileo-colic type did not occur—that is, the type in which, beginning in the terminal portion of the ileum, more and more of the ileum is prolapsed through a stationary ileo-cæcal valve, and thus the apex is constantly changing, which is peculiar to this type of intussusception only. Our so-called ileo-colic type began in the ileum a short distance above the ileo-cæcal valve, travelled down to and through the valve until the limit of the small intestine was reached, and then the cæcum and valve were pulled in and the tumour grew at the expense of the colon. The ileo-cæcal type came next in frequency. Here the apex was formed by the ileo-cæcal valve, but in two cases after reduction there was a distinct dimple in the postero-external portion of the caput cæcum, as if this were the starting point of the intussusception. The two cases of ileal intussusception are interesting in that they both began about 18 inches above the ileo-cæcal valve, and the apex travelled down to but not through the ileo-cæcal valve. In the case (20) with a two days' history, the cæcum and ascending colon were much more bound down to the posterior wall than usual, and the ascending mesocolon being very short, it would seem that this had some bearing on the intussusception not developing into an ordinary ileo-ileo-cæcal type. In the other case, with an eight hours' history, the cæcum and ascending colon were mobile, and perhaps if it had not been so early diagnosed would have developed into the ileo-ileo-cæcal type.

In all the 20 cases, except one, there was distinct mobility of the cæcum and ascending colon, and this undoubtedly is an important factor in the development of intussusception. Before an intussusception can become ileo-ileo-cæcal or purely ileo-cæcal there must be an ascending mesocolon.

D'Arcy Power has shown that the mesenteries of infants are relatively much longer than those of older children, and comparing the mesocolons of the intussusception cases with those of children of the same age seen at post-mortem, I think there is even greater mobility in the former cases.

Anatomically the ileo-cæcal valve would seem an ideal starting point for intussusception, especially if there is any tendency to prolapse of the valve, as then we would have a tumour, simulating a foreign body in the ascending colon, and thus exciting peristalsis.

The majority of these cases began in the ileum considerably above the ileo-cæcal valve, and also in three of the pure ileo-cæcal type it was found that there was a distinct dimple in the head of the cæcum, postero-externally, which seemed to have been the origin of the intussusception. The theory of irregular action of the muscular wall of the intestine, produced by some slight congestion or œdema of the wall, thus simulating a foreign body which the bowel attempts

the sheath and the entering layer, and gently dilating up, helped considerably. In one child reduction was attempted by means of hydraulic pressure. The abdomen was opened, and a large rectal tube passed, and water gently run in. By this means reduction was completed to within 2 inches, but as the pressure required seemed in danger of rupturing the bowel, the last part was reduced by direct manual pressure. The only advantage in this method is perhaps less shock, in that the bowel is not handled so much, but the delay in reduction does not warrant its use.

After-treatment.

All cases were given subcutaneous infusion of glucose, 2 per cent. in normal saline, immediately

TABULATED LIST OF CASES OF INTUSSUSCEPTION.

to pass, is the only theory that can explain this ileal formation of intussusception, but we must also have a certain mobility of the ascending colon before we can have formation along the usual lines.

Treatment.

The treatment of intussusception, provided the child is not moribund, is immediate laparotomy and reduction. The incision preferred is a right paracentral one, because in young children it takes no longer than splitting the rectus, and has the advantage of there being practically no bleeding and much less risk of hernia. Intussusception cases are also notorious for bursting their wounds, 5-10 days after operation, and the surgeon is faced with the pleasant duty of sewing up again after having sponged a cot-full of intestines free from threads and fluff.

The anæsthetic used in all but three cases was gas and oxygen with usually a certain amount of ether, and this anæsthetic has been found of great advantage in lessening shock. The children were fairly toxic, and thus easily anæsthetised; in fact, in four of the more toxic cases no ether was required at all. Usually, however, a little ether had to be given, and it was found that once the children were got to a certain depth of anæsthesia in this way they could be kept there with gas and oxygen alone. Gas and oxygen alone was never persisted with if there was much straining and protrusion of the bowel; also ether was usually given just before sewing up to relax the peritoneum and facilitate stitching.

The tumour, if very long, was partially reduced inside the abdomen, and then delivered, and the apical portion reduced. This portion was usually very congested, but by the use of a hot saline pad and gentle continued pressure reduction was easily obtained. If difficulty was still experienced, the introduction of a small pair of artery forceps between

after operation. This helped to lessen the effects of shock. Other points are: (1) that morphia was always given if the child seemed at all restless, and (2) that the child was not starved, being fed four to six hours after operation, if awake. In the more severe cases glucose water, 7 per cent., was given for 12 hours, before they were put on milk. The bowels were opened by small doses of castor oil, if they had not moved by the third day.

Conclusion.

Intussusception will always have a large mortality, as so much depends on early recognition, but once in hospital the points that seem to matter in its successful treatment are:—

1. Improve the general condition of the child, if bad, by infusion of glucose in normal saline.
2. Try to prevent further toxæmia and shock by: (a) gentle and speedy reduction; (b) gas and oxygen anæsthetic for operation; (c) subcutaneous infusion of glucose, 2 per cent. in normal saline, immediately after operation.

My thanks are due to the honorary surgical staff of the Hospital for Sick Children for their kind permission to publish these cases.

ROYAL SANITARY INSTITUTE.—A sessional meeting will be held on Friday and Saturday, Jan. 16th and 17th, in the City Chamber, Town Hall, Newcastle-upon-Tyne, when discussion will take place on Maternity and Child Welfare Practice; Cleansing and House Refuse Removal; Elimination of the Tuberculous Cow; and the Sanitation of the Cinema. The chair will be taken at 4 P.M. on Friday by Prof. H. R. Kenwood (Registrar). A reception will be held and various local institutions will be visited.

RECOMPRESSION OF A TUBERCULOUS LUNG BY ARTIFICIAL PNEUMOTHORAX

AFTER AN INTERVAL OF MORE THAN SIX YEARS.

By R. C. HUTCHINSON, M.D., D.P.H. MANCH.,
MEDICAL SUPERINTENDENT, ROYAL NATIONAL HOSPITAL FOR
CONSUMPTION, VENTNOR.

IN the treatment of pulmonary tuberculosis by artificial pneumothorax the time during which the lung should be kept compressed varies with each individual patient. One of the most difficult questions for decision is to estimate when the lung may be safely allowed to expand. Such decision is, as a rule, irretrievable, because in the majority of cases adhesions soon form between the lung and the chest wall, so that no recompression can be effected. A number of cases have been reported in which a fresh pneumothorax was induced after varying periods during which the lung had been allowed to expand. Vere Pearson¹ quotes one case in which the interval was two years, another of 15 months, and a third also of two years, but in this an appreciable amount of fluid was present in the chest. R. Burnard² quotes Dumarest, who succeeded in inducing a second pneumothorax after six months' interval, but a third attempt a year later failed. Burrell³ also gives an instance of recompression after six months' interval.

Clinical Record.

The case described below is of interest owing to the long interval between the last refill for artificial pneumothorax and a fresh induction. This patient had been resident in hospital on three previous occasions before her admission on April 11th, 1922. The notes are as follows:—

A. B., female, single, aged 25. The patient was admitted on Nov. 28th, 1906, with a history of enlarged cervical glands on the right side of the neck. Cough for six months. Hæmoptysis six weeks before admission. Loss of weight. Weight on admission 9 st. 12 lb.

Physical Signs.—Old operation scar right side of neck. Considerable thickening of the subcutaneous tissues and tenderness on pressure. Physical signs in the chest indefinite, suggestive of early infiltration of the right upper lobe.

The patient had a high temperature, and was confined to bed throughout her stay. The sputum varied from 2 to 6 drachms daily, and was repeatedly negative for tubercle bacilli. Weight on discharge (March 20th, 1907) 10 st. 3 lb. 4 oz.

The patient was readmitted on April 13th, 1908. She then gave a history of appendicectomy in July, 1907, and hæmoptysis amounting to 20 oz. in December, 1907. The physical signs were apparently unchanged. The patient had repeated attacks of hæmoptysis, and was confined to bed for the whole of her stay. The temperature chart showed daily hæmoptysis for the last two months, varying from staining of sputum to 3 oz. She was discharged on August 31st, 1908.

The patient was readmitted on Sept. 14th, 1915. She stated that she was well until the winter of 1914 when cough returned, and she had several attacks of pleurisy on the right side. She had been treated with tuberculin, sustaining marked reactions both local and general, and she stated that she had had pneumonia a month before admission. Weight on admission 9 st. 13 lb. Troublesome cough; no sputum. There was a pleuritic rub at the right base and post-tussive crepitations at the right apex in front. The patient was febrile, 100° F. nightly, and on Nov. 4th (seven weeks after admission) artificial pneumothorax (right) was induced. This was successful and refills were continued until March 14th, 1916, the patient being discharged on the 28th. The temperature remained at the same level throughout her stay, and she was confined to bed. The sputum varied from 2 drachms to 1 oz. daily, and once tubercle bacilli were said to be present, the remaining examinations being negative. Her weight on discharge was 10 st. 8 lb., a gain of 9 lb. The final examination revealed distant breath sounds at the right apex, respiratory murmur being absent throughout the remainder of the right chest. On one occasion she had stained sputum. Apparently compression was satisfactory. There is no record of X ray examination. She was discharged on

March 28th, 1916. The last refill of 1000 c.cm. was given on March 14th, 1916.

She was readmitted on April 11th, 1922. Her history was then as follows. After leaving hospital in 1916 she married and remained well until June, 1921, when she had ovariectomy performed. In February, 1922, she stated she had an attack of influenza and had since been confined to bed with a high temperature. Her weight on admission was 10 st. 2 lb. The physical signs consisted of marked impairment of note over the upper half of the right lung in front and the whole of the right lung behind, with deficient respiratory murmur throughout. No moist sounds present. The left lung presented no abnormal physical signs. On May 2nd, 1922, she had an attack of hæmoptysis, 1½ oz., followed by the usual staining of the sputum. Hæmoptysis recurred on May 15th, 19th, and 30th. On the 17th an attempt was made to induce an artificial pneumothorax on the right side. Three punctures were made, but no oscillation was obtained. Evening temperatures were in the neighbourhood of 100°. Further attacks of hæmoptysis occurred at the middle and towards the end of June. The physical signs at that time were as follows. Very poor air-entry in the lower three-quarters of the right lung, and the weak respiratory murmur clouded by numerous fine râles. The sputum was repeatedly negative.

On June 28th, 1922, a successful attempt was made to induce an artificial pneumothorax. Free oscillations were obtained and 150 c.cm. of air admitted. The pneumothorax was continued until discharge, which took place on Feb. 1st, 1923.

The patient, who was a large-chested woman, could accommodate refills of 1000 c.cm. to 1400 c.cm., the latter amount being given once only. The temperature continued to be irregular and did not appear to be controlled by the recompression which had been effected. The X ray showed complete collapse of the lung, and no physical signs could be found on the other side. The occurrence of slight attacks of hæmoptysis and periods of pyrexia after the compression was established gave rise to the suggestion that these were factitious. The most careful watch, however, failed to substantiate any grounds for a suspicion which still lingers.

After repeated negative examinations the sputum was found to be positive on Oct. 25th, 1922, and again a few days before discharge. Before the positive sputum was discovered it was thought possible that the recompression had been obtained in a non-tuberculous condition. The compression was continued until July, 1923, the patient attending for refills from Feb. 1st of that year, when she was discharged from hospital. She stated that she felt very much better since the treatment had been started. Her weight remained at 10 st. 2 lb., and she was "fat and well liking" in spite of continued pyrexia. On discharge the X ray examination showed that the lung was entirely free from adhesions and was completely collapsed on the mediastinum (see figure). On inquiry made in July, 1924, the patient stated that she had been working since January, 1924, as a dispensary nurse and had kept fairly well.

Summary.

The particular points of interest in this case may be summarised as follows:—

1. The interval between the last refill and the second induction was six years and three months.
2. The entire absence of adhesions in spite of a history of pleurisy and the presence of a pleuritic rub in September, 1915, is a minor point of interest, confirming one's clinical experience that sufficient pleural space for a successful pneumothorax is sometimes found even where there has been a history of

previous pleurisy. In other words, the opinion is confirmed that the possibility of inducing artificial pneumothorax is best estimated by attempting to carry it out, despite the deterrent influence of the medical history.

The refills in this case were continued at the patient's home until December, 1923, when she voluntarily terminated her treatment.

TROPICAL SPRUE AND PERNICIOUS ANÆMIA.

ÆTIOLOGY AND TREATMENT.

By C. ELDERS,

THE HAGUE; LATE DIRECTOR, GENERAL HOSPITAL U.L.P.C., SUMATRA.

Resemblances of Sprue and Pernicious Anæmia.

IN 1897 Thin, in his book on Psilosis, said:—

"I have known cases mistaken for pernicious anæmia by medical men who had never seen the disease and who were not aware of its existence; and I have had the diagnosis of pernicious anæmia insisted on in one of my own cases by a physician in London."

Thin found a high colour-index in three cases of tropical sprue. Carnegie Brown, in his treatise on "Sprue and its Treatment" of 1908, said:—

"Toxæmic sprue, especially when seen in England, is liable to be mistaken for progressive pernicious anæmia. Confusion between two such well-marked clinical conditions might be thought improbable, but, as a matter of fact, the mistake is one that is by no means unlikely to occur."

Bassett-Smith, Low, Manson-Bahr, Schilling-Thorgau, and others examined cases of sprue, whose blood picture was that of pernicious anæmia. In 1918 Nolen,¹ who is quite familiar with both diseases, went so far as to declare that it was sometimes impossible to distinguish sprue from pernicious anæmia. In some cases he found the complete blood picture of pernicious anæmia; in others only the high colour-index of sprue. He pointed out that Carnegie Brown's criteria for the differential diagnosis of the two diseases did not hold good. Gradually nearly all the peculiarities of the blood picture of pernicious anæmia were found in tropical sprue.

Relations of Sprue and Pernicious Anæmia as Deficiency Diseases.

As I² had since 1916 defended the view that sprue is a deficiency disease, the study of the interrelation of both diseases had attracted me greatly, principally in connexion with the ætiology and treatment of pernicious anæmia. In 1922³ I published a study on the blood of 11 cases of tropical sprue. In nine cases there was found at times a colour-index higher than 1, and where it was lower than 1 this could be explained by hæmorrhages from hæmorrhoids. I came to the conclusion that the blood picture could not well be distinguished from that of pernicious anæmia, and that the tongue changes, as Morawitz⁴ had recently described them, could not properly be distinguished from those in pernicious anæmia. In sprue, as in pernicious anæmia, there is often no hydrochloric acid in the gastric juice. There are gastro-intestinal disturbances in both diseases, though they are more prevalent in tropical sprue. I criticised the view that pernicious anæmia is caused by infection or intoxication of exogenic or endogenic origin, and that there is a hæmolytic poison, and I trust I was able to show that certain well-recognised features in pernicious anæmia cannot be satisfactorily explained by an intoxication hypothesis, while the same facts and all the others are easily explicable on a deficiency hypothesis. There is only a slight difference between the two diseases, and if one is a deficiency disease

the other should be so too. I have had opportunities of studying more cases of sprue since then, and the more I have studied the diseases the stronger has grown my belief that the blood and other symptoms are similar. Even symptoms such as pigmentation like that found in Addison's disease, petechiæ, and mental disturbances, which are not found in every case of pernicious anæmia, may be found occasionally in tropical sprue. Though there has not yet been found in sprue the degeneration of the posterior or lateral columns of the white substance of the spinal cord which occurs in pernicious anæmia, I have seen a case of sprue with ataxia* and anæsthesia of both legs. The knee-jerks could be hardly demonstrated. Thin found the reflexes in sprue sluggish. I can confirm this. He saw two cases with peripheral neuritis of the lower extremities. Maurer saw a case complicated with beri-beri.⁵ If we remember that Dürck found degeneration of the posterior columns of the spinal cord in beri-beri, which points to the view that degeneration of the posterior columns of the white substance of the spinal cord in deficiency-diseases is interchangeable with degeneration of the peripheral nerves, there are some grounds for expecting degeneration of extra- or intra-spinal nerve fibres in some cases of tropical sprue as in pernicious anæmia. Recently there was found, in the laboratory of Prof. Tendeloo at Leiden, red bone marrow of the long bones in a case of sprue, as is common in cases of pernicious anæmia, and in another case in the same laboratory there was found post-mortem gelatinous bone marrow, as is common in aplastic anæmia. As in my view there is no essential difference between pernicious and aplastic anæmia, these findings support the belief that there is a close relation between pernicious anæmia and tropical sprue.

Diet as a Causal Factor in Tropical Sprue.

From the anamnesis of tropical sprue one is often able to show that patients have lived on an unbalanced diet before contracting the disease, and it is a well-known fact that the food of Europeans in the Dutch Indies contains too much cured rice and canned meat, often little fresh meat, and is probably poor in fat-soluble A and water-soluble B. Dr. Bailey K. Ashford⁶ pointed out that the food of the population of Porto Rico with those classes where tropical sprue is common, is poor in animal proteins and fat-soluble A.

During nearly ten years I have not lost a single case of tropical sprue under my care, and even the severest cases were cured or greatly improved by a proper diet, consisting of underdone meat up to 1 kg. or more, with 1½ to 2 litres of raw milk with aquacalcis 5 times a day 15 c.cm., 15 or 30 c.cm. of cod-liver oil, and a few oranges or 400 g. of strawberries a day. The case of pernicious anæmia also greatly improved on this diet. All this seems to point to the conclusion that sprue and pernicious anæmia are closely related, and that sprue is a curable deficiency disease. If sprue is a deficiency disease it is probable that pernicious anæmia is a deficiency disease also. According to my opinion there are only the following real differences between the two diseases. Though there are gastro-intestinal disorders in both, these may be absent in pernicious anæmia and are more serious in tropical sprue. In tropical sprue there is more fermentation in the intestinal canal, and commonly there are produced acid and gas. The reaction of the motions to litmus is acid. In association with this there is a higher degree of emaciation in tropical sprue. Fat is not properly digested in sprue. To explain these differences in my way of thinking, one may say that the deficiency in the food which is the cause of the diseases, is for the greater part common to both and in a small part different. To cure sprue experience has shown that animal proteins, with vitamins and perhaps salts, are very useful. I hope these will be useful in the treatment of pernicious

* Two neurologists saw this case, Dr. van Braam Hoekgeest thought there was ataxia, Dr. de Vries thought there was a pseudo-ataxia.

anæmia too. From the experiments on rats of Mottram, Cramer, and Drew,⁷ we know that in rats lack of fat-soluble A and water-soluble B in the food makes fat transport through the intestinal wall impossible, and leads to atrophy of the intestinal wall. As I have said already, we know from experience that the fat absorption is highly disturbed in sprue, and atrophy of the intestinal wall is described by several investigators. From this it seems possible that lack in fat-soluble A and perhaps water-soluble B plays a more important rôle in sprue than in pernicious anæmia.

indifferent success, and sent her under my care on Jan. 1st, 1924. Condition on this date: Pale old lady. Abdomen ballooned, percussion tympanitic. Radial arteries tortuous, rigid, with bead-like patches of induration, systolic pressure 140 mm. Hg. The liver dullness is reduced. The spleen is not enlarged. The tongue is painful, smooth, and red at the edges. The motions are greyish, watery, or semi-solid, with gas bubbles and acid. There is much rumbling in the abdomen, cedema at both ankles. She got a dose of ol. ricini to empty the bowels, and was put on a diet of raw milk with aqua calcis, oranges, and a little meat. After two days the abdomen was flat and soft, and the motions were greyish-yellow. The tongue was painless. On Jan. 12th she went to hospital. The body-weight was

Clinical Cases.

To illustrate the effect of my diets I shall give a few particulars of two cases of tropical sprue and one of pernicious anæmia.

CASE 1.—Mrs. N, 67 years, was born in Java, suffered from amebiasis, married at 19, had for 30 years at least weak bowels, suffered from cystitis. Her doctors treated her with rice, sago, and other farinaceous foods. Milk, meat, and fruit were not allowed. She had four children, which she was not able to nurse herself. When at Palembang (Sumatra) she was very fond of canned delicacies, which she preferred to fresh meat, fowl, or fish—even turtle from the country. In addition she ate polished rice. In the Dutch Indies it is difficult to get fresh milk. Three years ago she came to Holland. On board ship she improved greatly from her painless diarrhoea. Three months ago she had a serious relapse. Her last doctor treated her with

45.4 kg., and her height 143 cm. Here she got 1½ litres raw milk with aqua calcis, 100 g. cheese, 3 to 5 tangerines, 15 c.cm. of cod-liver oil, and 50 g. of underdone meat a day. Later on the meat was temporarily replaced by yolks of egg—up to six a day. In February I tried beans, cabbage, carrots, which I had to stop again. On Jan. 23rd she had the first solid stool. From Feb. 19th the albuminuria diminished rapidly, and there was only a trace on March 3rd. The general condition had greatly improved. The stools were satisfactory. From April 4th she got, besides milk, underdone meat, yolk of egg, and cod-liver oil, and instead of oranges strawberries. Body-weight increased from 45.4 kg. on Jan. 12th to 50 kg. on June 23rd.

On April 25th the patient was suffering from a furuncle, which may explain the high number of leucocytes on this date.

This was a serious case of tropical sprue with complications. The anamnesis shows clearly that she had lived on an inadequate diet. The blood table shows the effect of diet and rest.

CASE 2.—Man, aged 44, had never liked eggs, milk, meat, fish, fowl, and vegetables. He never had a good appetite. In 1922 he was treated for pernicious anæmia in the hospital in The Hague, leaving it at the end of September. I am indebted to Dr. de Jongh for the three blood counts of this period. His body-weight fell in hospital from 63.5 kg. to 61.8 kg. When in hospital he was on ordinary diet and was treated with arsenic. He had never been in India or other tropical countries, and had no diarrhoea. I examined him for the first time on Nov. 16th, 1922, for which I have to thank Dr. Wigger Boelens and Dr. Rombouts. He complained of a sore tongue, felt always sleepy, had anæsthesia in both legs. His gait was uncertain. He complained of pain in his legs and had swollen feet. His height was 182 cm., and his weight 70 kg. He thought he had improved after having left hospital. Dr. Rombouts prescribed for him arsenic, iron, milk, and eggs. I prescribed him a diet with three ounces of underdone horse-meat, milk, eggs, fruit, and cod-liver oil. He said he could not afford it, and he did not come back. Still he kept to my diet as well as he could. To Dr. Wigger Boelens I am indebted for the blood count of Oct. 10th, 1923. Dr. Wigger Boelens found his general condition then very good. By kind permission of Dr. Rombouts I had the opportunity to examine him again on June 15th, 1924. He was then in good condition and had done service in a Red Cross Brigade in the dunes as well as other men, though he thought he perspired too much. His tongue was not sore at all, though he told me it sometimes felt sore, for instance, after a dinner party. His body-weight was now 80 kg.

Of 140 polymorphonuclear leucocytes 103 had the nucleus too far fragmented (Armeth). The latter symptom was found in sprue by Schilling-Thorgau. Wassermann's and Sachs Georgi's tests were negative. The story shows clearly that the man had lived during his whole life on an inadequate diet.

CASE 3.—Man of 60 years, lived for many years in Java, very severe case of tropical sprue. To save space I only give the body-weights and the blood counts. The diet did not differ from that of the other cases. From the history it was not so clear as in the others that he had lived on a deficient diet, but the food of most Europeans in Java is not what it should be from the point of view of the newer knowledge of nutrition, and he suffered from chronic dysentery, for which his doctors gave him unsuitable diets.

From Sept. 26th he took, against my advice, ordinary boarding-house food. After Dec. 27th he kept again to the meat, milk, fruit, cod-liver oil diet. His weight increased gradually from 57 kg. on June 26th to 83 kg. on Feb. 29th.

The blood table shows that under the influence of the sprue diet there was gradual improvement in the anæmia. Besides his diet he got 20 injections of sodium cacodylate and a little hydrochloric acid with pepsin. He used to be the weakest man of his family, now he is the strongest.

Other cases of sprue are cured in the same sure way. To this list and to that of 1922 I could add a few cases more of tropical sprue. In reference to the high colour-index my findings are confirmed by van der Scheer,* who has published a series of cases. Koolemans Beynen found the high index also in nearly all his cases. He confirmed the sure effect of these diets. I hope that this will serve to direct attention to these views and treatment, and that some may be encouraged to try these diets in cases of pernicious anæmia.

Conclusions.

Sprue is a deficiency disease. A high colour-index of the blood is a common occurrence in sprue. Sprue and pernicious anæmia have so much in common that it is difficult to accept a different ætiology for the two diseases. If they have the same ætiology it is most probable that pernicious anæmia is, like sprue, a deficiency disease, and as such should be curable, or at least amenable to improvement by well-chosen food.

Clinical and Laboratory Notes.

DIABETIC COMA WITHOUT KETONURIA.

By GRIFFITH EVANS, F.R.C.S. ENG.

IN view of the report under the above heading in THE LANCET of Dec. 6th, I feel that the under-mentioned case is worthy of record for the following reasons: 1. Long-standing diabetes was so modified by insulin that sugar disappeared from the urine and approximated the normal level in the blood. 2. The patient, nevertheless, died in coma, with evidence of unusual disturbance of the central nervous system.

The patient was a male of 72, the salient features in his history being glycosuria and ketonuria of many years standing, the former as high as 20 per cent., but controllable to some extent by dieting, and, in 1912, a severe attack of præcordial pain, which was treated as angina pectoris. In July, 1924, he complained of pains in the arms, lassitude, and slight general malaise. There were slight swellings of some finger-joints, fibrotic nodes at deltoid insertions; blood-sugar 275 mg. per 100 c.cm.; urinary sugar 5 per cent.; trace of ketonuria. August 8th-Sept. 15th: Insulin given daily, 10-20 units, dose controlled by urinary sugar, which disappeared on the latter date, and did not return till Oct. 21st, when pains were increasing, and there was also slight ketonuria. Insulin (10 units) was given for four days, when the sugar finally disappeared. Nov. 7th: Pains very severe, skin of arms hyperæsthetic, transient tenderness over scapulae and cervical spine. Very restless. Blood-sugar 142 mg. per 100 c.cm. No glycosuria; no ketonuria. Ammonia nitrogen (urine) 0.058. Dec. 1st: Stiffness of arms and legs appearing, intermittent delirium, and delusions. Pain as before. Calf muscles seen contracted and in fibrillation. Dec. 5th: Died after two days' coma, with pyrexia 101° F., head retraction, stiff arms and legs, Cheyne-Stokes breathing. The plantar reflexes were flexor throughout; there were no retinal changes, and after Oct. 25th the urine remained free from sugar and acetone.

It is inconceivable that diabetes of such long standing should have been cured by insulin in small doses over a short period. *Pari passu* with the suppression of glycosuria there appeared signs of irritation of the central nervous system—disseminate and not conforming to any well-known clinical type. Unfortunately no specimen of cerebro-spinal fluid was taken, since the possibility of there being ketosis confined to it was not realised until after the patient's death. I feel justified, however, in publishing these admittedly incomplete notes, if only to emphasise the necessity of examining the cerebro-spinal fluid for sugar and acetone, even when the blood and urine remain free.

Carnarvon.

A CASE OF MEMBRANOUS STOMATITIS IN AN INFANT SIX MONTHS OLD.

By J. W. TOMB, O.B.E., M.D., D.P.H. DUB.,
MINES BOARD OF HEALTH, ANSANSOL, BENGAL, INDIA.

THE rarity of diphtheria in infants so young as was the subject of the following note warrants my placing this case on record:—

The patient was an English bottle-fed female infant of 4 months, who developed "blood dysentery," for which she was under treatment for about two months. On the disappearance of the dysentery a few spots of "thrush" began to appear on the child's tongue. These, on medical advice, were treated with glycerine of borax and peroxide of hydrogen, but in spite of treatment continued to spread over the mucous membrane of the tongue, cheeks, and lips. When first seen by me large areas of the mucous membrane were covered with a thick, whitish, closely adherent membrane which, on removal, left a raw and bleeding surface underneath, with rapid reappearance of the membrane. The fauces were, however, quite uninvolved, as was also the posterior portion of the buccal cavity, the membrane displaying a marked tendency to grow forwards over the

mucous membrane of the lips rather than backwards over the fauces. The buccal cavity was abnormally dry and salivation defective. The child, who had an ill-nourished and marasmic appearance, was extremely weak and cried feebly.

Such being the child's condition, it was decided, owing to the clinical characteristics of the membrane, to treat it as diphtheritic without further delay, notwithstanding the fact that the fauces were quite uninvolved and diphtheria in infants of that age almost unknown. Accordingly, 4000 units of anti-diphtheritic serum were injected subcutaneously.

The result wholly justified the action taken, as the membrane, which up to that time had persistently continued to spread in spite of all local treatment, completely disappeared within 36 hours.

Medical Societies.

BRIGHTON AND SUSSEX MEDICO-CHIRURGICAL SOCIETY.

At a meeting of this Society, held on Jan. 1st, Dr. E. F. MAYNARD, the President, in the chair, Mr. D. A. CROW read a paper on the

Possibilities of Peroral Bronchoscopy and Oesophagoscopy.

He outlined the work done by Dr. Chevalier Jackson and his associates in the bronchoscopic clinic in Philadelphia. Lung abscess drainage, the diagnosis and treatment of neoplastic, cicatricial, and spasmodic stenosis of air and food passages, and illustrative cases of foreign body problems were briefly described. As an illustration of the detailed study necessary for undertaking foreign body removal, Dr. Jackson's methods of removing an open safety-pin were considered in some detail. Distinction was emphasised between, on the one hand, foreign bodies requiring urgent treatment such as those potentially or actually obstructive to the air passages, also vegetable substances—e.g., nuts, which caused intense reaction and, on the other hand, those requiring less urgent treatment, such as the non-obstructive metallic bronchial foreign body, the presence of which was constantly being overlooked (in the absence of a radiogram) in cases diagnosed as phthisis or bronchiectasis. These cases would at once recover after bronchoscopic removal of the foreign body. Mr. Crow asked that those throughout the country who were seriously willing to undertake bronchoscopy should have plenty of opportunity to acquire the necessary perfection of the very complex technique of endoscopy.

Discussion.

The PRESIDENT referred to the rapidity of recovery of abscess after removal of a foreign body. In bronchoscopy, he said, we had a very valuable aid to diagnosis in cases where no organic disease of the lung could be found by ordinary clinical methods and in cases of lung abscess.—Mr. A. J. HUTCHISON discussed the earlier methods of bronchoscopy and oesophagoscopy as practised in Vienna. He considered oesophagoscopy should be employed much more frequently than at present in cases of dysphagia.—Mr. L. A. PARRY asked if Mr. Crow advocated that swallowed foreign bodies which had passed into the stomach should be removed by the mouth. Of 20 cases in his experience in only one case, that of a latchkey remaining in the stomach seven days, was it necessary to operate abdominally, in all the others the obstruction passed naturally per rectum.—Mr. H. N. FLETCHER asked what were the possibilities of operation by bronchoscopy on abscesses of the lung which were usually situated in the lower lobe.—Dr. NEVILLE COX spoke with reference to non-opaque foreign bodies in the bronchi.—Mr. CROW, in reply, referred to the rarity of foreign bodies being coughed up from the bronchi (2 per cent. only). He considered that gastroscopy

was not required for foreign bodies in the stomach, and that abscess of the lung could be dealt with very successfully by bronchoscopy.

Mr. J. R. GRIFFITH read a paper, illustrated by lantern slides, on the

Eradication of Diseased Tonsils and Adenoids.

He described Mr. Waugh's method of removing tonsils by means of blunt dissection, and claimed that the method was clean and accurate and almost bloodless, that it avoided injury to the pillars of the fauces with their contained muscles, and that it avoided also the danger of aspiration of blood into the larynx and trachea. It was important, he said, to make the primary incision in the right place so as to ensure exposing the capsule at once. The blood-vessels were exposed entering the capsule before they were divided, and bleeding was completely stopped by gauze pressure over the divided ends of the vessels. The technique of the last part of the operation was important so as to ensure removing the whole of the lingual pole and at the same time avoid injuring the base of the tongue. The adenoids were then removed with a La Force adenotome, an instrument built on the guillotine principle. The window was curved to fit the superior and posterior walls of the nasopharynx, the cutting part was furnished by a flexible steel blade running in grooves in the window frame. This instrument cut through the adenoid attachment cleanly without tearing the mucous membrane. As a rule bleeding was very slight, and stopped after the nasopharynx had been mopped out two or three times. Mr. Griffith claimed that the results obtained by these methods were superior both anatomically and functionally to those he had obtained previously by enucleating with Sluder's reversed guillotine, although before adopting Mr. Waugh's method he was perfectly satisfied with the guillotine.

Discussion.

Mr. HUTCHISON said he preferred the reverse guillotine for children under 12 years of age. The disadvantages of the Waugh operation were the deep anæsthetic required and the length of operation. Also, if the incision was not made in the exact line, more damage was done to the pillars than by reverse guillotine.—Mr. CROW said he always employed Waugh's method in children and adults, but did not stitch pillars of fauces.—Mr. H. SEYMOUR said he used to adopt Willis's method, but was now quite converted to Waugh's method since seeing Mr. Griffith operate.—Mr. F. E. FEILDEN stressed the importance and difficulty of getting into the right layer and the importance of getting outside the capsule. He did not think it was so suitable for children as for adults.

Mr. GRIFFITH, in reply, said he considered there was less danger in deep anæsthesia by ether than light anæsthesia with possible laryngeal spasm. Bleeding might be very serious when the reversed guillotine was used.

Exhibition of a Case and Specimens.

Dr. A. W. WILLIAMS showed a very interesting case of extensive *Pityriasis Rosea*, involving the whole trunk and limbs down to the elbows and knees. The rash had cleared, but the areas were left deeply pigmented due to arsenic which had been exhibited in small doses before the case came under Dr. Williams's notice. The Wassermann reaction was negative.

Dr. H. M. GALT showed microscopical slides of normal tonsil, tuberculosis of tonsil, and squamous epithelioma of tonsil.

ROYAL INSTITUTE OF PUBLIC HEALTH.—The Harben lectures will be delivered in the lecture theatre of the Institute, 37, Russell-square, London, W.C., by Prof. Edgar L. Collis on Phthisis and Industrialism (National and Occupational) with Reference to Other Infectious Diseases. The first lecture will be held on Monday, Jan. 26th; the second on Tuesday, the 27th; and the third on Wednesday, the 28th, at 4.30 p.m. respectively. These lectures were unavoidably postponed from November, 1924. No tickets of admission are required.

Reviews and Notices of Books.

MENTAL DISEASES.

The Borderland. Some Problems of Insanity. By THEO. BULKELEY HYSLOP, M.D., C.M., F.R.S. Edin., late Senior Physician, Bethlem Royal Hospital. London: Philip Allan and Co. 1924. Pp. 310. 32s. 6d.

THIS volume contains four distinct elements, which, perhaps to its detriment, are not subdivided. Chapters 1 to 4, 11, 16, 18, 19, and 21 describe varieties of insanity from a purely academic standpoint; Chapters 5 to 10, and 17 deal with factors attendant on European civilisation which, in the author's opinion, are threatening the mental stability of the race; Chapters 12, 13, and 14 compose an interesting essay on decadence in art; Chapters 15, 20, and 22 form a miscellaneous group, of which the former is a highly erudite philosophical discourse, and the latter deal respectively with divorce, and what may be termed the mental sociology of the future.

A good deal of public attention has been directed to Dr. Hyslop's views under the second heading. To summarise them, he believes that the mental well-being of the British race is deteriorating under the influence of alcohol, noisy surroundings, over-education in relation to mental capacity, and the strenuous competition for livelihood among an overcrowded population, many of whose immediate forbears were accustomed only to an agricultural existence. This contention raises numerous issues of practical and general interest, and several individual points whereon the author will meet a large body of disagreement. To take a minor example, the argument that exposure to continued noise may determine meningeal thickening over the auditory area rests on very insecure foundations. Apart from alcohol, whose part in this matter demands (and has more than once received) a volume to itself, the remainder of these factors conform to the hackneyed description "mental stress," and it must be generally agreed that their influence, at all events, is by no means abating. A conclusion, however, of the first importance, at which Dr. Hyslop appears to have arrived, is that mental "unfitness" (whether neurotic or psycho-neurotic) is increasing, and to an extent which threatens us with frank racial degeneracy. Here is a subject worthy of the fullest debate. There is as yet no statistical evidence as to the incidence of mental deficiency and degeneracy, nor, since the latter term includes such conditions as drug addiction and neurasthenia, can we reasonably expect ever to be supplied with it. The country is certainly better fed, clothed, housed, and exercised than in, say, 1875: is it, or is it not, true that these physical advantages are being neutralised by influences whose action is on the mind?

The author's very numerous interests and accomplishments must, unfortunately, be blamed for the fact that this book embodies too great a variety of subject-matter for the average reader's mental digestion. He will be unable to resist the conclusion that its author has seized a single opportunity for airing all the convictions and prejudices of a life-time. He will admit, on the other hand, that a social problem of vital importance has been presented with surpassing force and authority.

A Present-day Conception of Mental Disorders. (Harvard Health Talks, 12.) By CHARLES MACFIE CAMPBELL, M.D., Professor of Psychiatry in Harvard University. Harvard University Press. London: Humphrey Milford. 1924. Pp. 54. 4s. 6d.

THIS small volume depicts insanity as a human ailment to be regarded in the same light as any other form of disease. As a simple account of what we know of the aetiology of mental disease it could hardly be bettered for lucidity and sweet reasonableness, and its effect in removing prejudice and ignorance in this connexion should be in direct proportion to its circulation.

TROPICAL DISEASES.

Exotische Krankheiten. A Short Practical Handbook. By Prof. Dr. Med. MARTIN MAYER, Departmental Director of the Institute of Marine and Tropical Medicine and Privatdozent in the University of Hamburg. Berlin: Julius Springer. 1924. Pp. 304. 24 gold marks.

THE object of this publication (as stated in the preface) is to provide in small compass a practical handbook, shorn of lengthy theoretical considerations. Designed primarily for the ships' surgeon and for physicians practising abroad, it condenses much of the information contained in the third edition of "Mense" recently reviewed in THE LANCET.

The title "exotic diseases" is happily chosen, for many of these peculiar infections (such as Rocky Mountain fever and tsutsugamushi) are not necessarily tropical in origin. Special attention has been given to the illustrations which, so far as possible, have been made from photographs. Emphasis is laid upon treatment, while but scanty reference is made to the literature. The protozoal diseases included in the work, malaria, trypanosomiasis, and amoebiasis, are amongst the most characteristic in tropical medicine, and spirochaetal diseases are well represented, while those due to bacteria include plague, cholera, Malta fever, and leprosy. Infectious diseases of uncertain nature comprise dengue, verruga peruviana, and alastrim. The inclusion of such a problematical condition as "bronchial spirochaetosis" seems inadvisable, and there appears to be little ground for differentiating the "pseudotyphus of Sumatra" from tsutsugamushi. The helminthic and arthropod infections occupy a considerable, even a disproportionate, space, while fungus and skin diseases, some of great rarity, are also noticed. The book closes with an account of snake, fish, and reptilian poisons, and the various forms of heat-stroke. We note that the subtertian malaria parasite is referred to as *Plasmodium immaculatum*, a terminology generally regarded as obsolete, while criticism may be directed towards certain figures, such as the representations of *Entamoeba histolytica*, which would be well replaced by more modern drawings. The coloured plate of helminth eggs in the faeces, drawn to scale, supplies a real want. The therapeutic sections might well be more complete, especially in the dramatic and acute infections, and it is a pity that, by limiting himself to the title of the work, the author has had to omit such an important disease as bacillary dysentery.

These are but minor blemishes, for, on the whole, this small volume well fulfils its aim.

REJUVENATION.

By NORMAN HAIRE, M.B., Ch.M. London: George Allen and Unwin, Ltd. 1924. Pp. 223. 7s. 6d.

THE subject of rejuvenation has aroused widespread interest during the last four years, and has stirred the popular imagination. Dr. Haire has produced a work which will be acceptable to the educated layman who wishes to obtain information on this subject. He has avoided technical terms and has written in a language which should be easily comprehensible to non-medical readers. The experimental work of Steinach and Serge Voronoff is briefly described, and an explanation is given of the theory on which rejuvenation operations are based. In the latter half of the book the results obtained from testicular grafts by various surgeons, Lichtenstern, Voronoff, Peter Schmidt, Lespinasse, and Kenneth Walker, are tabulated and the case-sheets of their patients published in detail. In the last chapter these results are reviewed and certain conclusions reached. No exaggerated claims are put forward for either grafting or vasotomy, and the author maintains a critical attitude. So many misleading statements have appeared in the public press that a book expressing a well-balanced judgment is of value.

SYPHILIS.

Le bismuth dans le traitement de la syphilis.
By C. LEVADITI. Paris: Masson et Cie. Pp. 316.
Fr. 25.

FOLLOWING on some experiments on bismuth in the spirillosis of fowls, which were carried out by Sauton and Robert—researches which were tragically interrupted—Sazerac and Levaditi, of the Institut Pasteur, succeeded in showing that bismuth was of value, not merely in the treatment of syphilis of rabbits, but in syphilis of human beings.

It is now three years since bismuth gained a footing in the therapy of syphilis, and during this period the literature on the subject has grown to such dimensions that Levaditi has considered the time opportune for this monograph on the subject. In this volume the whole history of the experimental work carried out is fully set forth. The choice of the compounds used, their toxicity and elimination from the body are freely discussed in the light of the experimental work on rabbits and fowls. The major part of the work is, of course, devoted to the employment of the drug in the treatment of syphilis in the human being in all its stages. The effect of bismuth compounds on the serum reactions is fully dealt with and conclusions are set down with moderation. The work is a practical and complete handbook on the subject, and is, moreover, authoritative.

THE PHILOSOPHY OF WITCHCRAFT.

By IAN FERGUSON. London, Calcutta, and Sydney: George G. Harrap and Co., Ltd. 1924. Pp. 219. 5s.

THE author of this little book presents the witch not merely as an actual personage but as a sample of the predominant instinct towards what he terms "the philosophy of comfort"—that is to say, that the witch appeals, whether in medicine, ritual, or literature, to what is popular rather than what is scientific or arduous. The opening chapter, which traces the historic progress of the witch from a stockade captive to wise woman, to prophetess, and finally to a servant of the Prince of Darkness, indicates the range over which the author's knowledge and fancy play. While he disclaims specially any pretensions to having furnished an academic contribution to a vast subject, he has certainly outlined that subject in a way which will make those interested approach it intelligently. A wide-ranging bibliography is appended for the use of such. We have read this suggestive and unpretentious little work with considerable pleasure, and we recommend the perusal of the chapter on the depreciation of spiritual values to those who are pained by certain modern developments of spiritualism.

VOLUMETRIC ANALYSIS.

A Systematic Handbook of Volumetric Analysis.
Eleventh edition. By FRANCIS SUTTON, F.I.C., F.C.S. Revised and enlarged by W. LINCOLNE SUTTON, F.I.C., Public Analyst for the Counties of Norfolk and Suffolk, Norwich, Ipswich, &c.; and ALFRED E. JOHNSON, B.Sc. Lond., F.I.C., A.R.C.Sc.I., Additional Public Analyst for the County of Stafford and the Borough of Wolverhampton. London: J. and A. Churchill. 1924. Pp. 629. 35s.

THIS classic of chemistry was first published in 1863 and the author, Mr. Francis Sutton, who was well over 80 years of age, had the gratification of signing the preface of the tenth edition in 1911. He was not spared to see the present edition. Few authors are fortunate enough to see their book flourishing during 50 years. In this period the many suggestions made to the author have been received in good part and acted upon, with the result that to-day the volume is very good indeed.

The general arrangement of the book remains unaltered. It is divided into nine parts. The first

deals with the general principles of measuring, weighing, &c. Part II. concerns acidimetry and alkalimetry. The authors have neglected to emphasise the importance of the ionic dissociation theories, particularly with regard to the theories of the action of indicators. There is no account of conductivity methods, and although it might be held that these do not come within the scope of the book, a description is necessary to a thorough understanding of these problems. Parts III. to IX. deal respectively with analytical methods depending upon oxidation and reduction, precipitation, the application of these methods to inorganic and organic substances, and the analysis of urine, water sewage, and gases. The latter section is undoubtedly one of the finest descriptions of methods of gas analysis. The volume concludes with a series of useful tables.

We wish the volume every success, and congratulate its producers upon a well-earned jubilee.

Elementary Qualitative and Volumetric Analysis.
For Medical First-year University Science Students, &c. By WILLIAM CALDWELL, M.A., Sc.D., Professor of Chemistry, Royal College of Surgeons in Ireland. With an Introduction by C. S. GIBSON, O.B.E., M.A., M.Sc., F.I.C. London: J. and A. Churchill. 1924. Pp. 418. 10s. 6d.

THIS volume aims at giving the medical student as complete a course in chemical analysis as is necessary for the preliminary examination of either the Conjoint Board or a university. The author has attempted to raise the subject to a higher plane than a mere string of tables. Throughout the book the subject is presented in such a manner that the student performs his analyses rather in the guise of studying reactions than in the light of a competition, which is usually the medical student's idea of this branch of his activities. The book embraces inorganic analysis, together with simple organic reactions. Thus tests for fats, proteins and carbohydrates, and the reactions of some typical alkaloids are included. The volumetric analysis covers all the ground required for the student, and deals also with some estimations necessary for the chemical examination for the D.P.H. There is a remarkably clear account of the theory of the action of indicators, and of hydrogen-ion concentration. The author, in his laudable zeal for simplicity, has, perhaps, made rather a mistake in suppressing the easier mathematical aspect of this subject. Thus, his description of the meaning of the symbol pH is unintelligible. The book, on the whole, however, is admirably written, and certainly marks an advance in the teaching of elementary students.

ANÆSTHESIA FOR NURSES.

By Colonel WILLIAM WEBSTER, D.S.O., M.D.
London: Henry Kimpton. 1924. With illustrations. Pp. 153. 10s. 6d.

IN spite of its ambiguous title and its multiplicity of split infinitives this is a good little book. It tells the nurse most of the things which she should know in connexion with anæsthetics and a good many details which are doubtless welcome to nurses working in the country from which Colonel Webster writes, where the nurse frequently acts as anæsthetist on her own responsibility. A small chapter is devoted to ethylene, the latest recruit to the band of general anæsthetics, and the statement is made that recovery with this drug is as rapid as with nitrous oxide. This is not accurate of long administrations. In the description of chloroform administration by mask and drop-bottle no mention is made of the important factor of the distance of the mask from the face. Presumably the two are in contact from the first, and the nurse is not impressed with the fact that danger from overdose can be avoided by the simple measure of not letting the mask touch the face. In describing the preparation of the patient beforehand

Colonel Webster adopts a more rigorous starvation procedure than is now usually favoured. All his directions bearing on the patient's comfort and on what we may call the nurse's social relation to her patient are excellent. His punctiliousness here is illustrated by the direction that "sacred emblems worn about the neck may be retained unless the operation involves this part of the body."

LE PROBLÈME DU CANCER.

By WILLIAM SEAMAN BAINBRIDGE, A.M., ScD., M.D., C.M. Louvain: A. Uystpruyst. Paris: O. Doin. 1924. Pp. 479.

THE French translation of Prof. Bainbridge's treatise on cancer, which first appeared in English in 1915, has reached a second edition and is now published in Paris as well as in Louvain. This book has the distinction of being the first one to be turned out from the printing press of Trois Rois at Louvain after reconstruction, for the press was destroyed at the beginning of the war by the Germans. The King of the Belgians accepted the first copy from the Trois Rois, the printing house of the University of Louvain. The second French edition has been revised and added to, and we hope that the French public will note one of the final chapters, which deals with the education of the laity. Prof. Bainbridge perceives clearly that in organised attempts to deal with the cancer problem the coöperation of the public must be obtained.

THE STUDY OF CORALS.

An Introduction to the Study of Corals. By SIDNEY J. HICKSON, Professor of Zoology in the University of Manchester. Manchester University Press. London: Longmans, Green and Co. 1924. Pp. 257. 25s.

IN this book Prof. Hickson has provided a useful up-to-date survey of the various organisms loosely grouped together in popular speech as "corals." Although dealing somewhat technically with descriptive classification in nine out of the 12 chapters, the book is pleasantly written and does not demand of the reader more a priori knowledge than is afforded by the brief zoological course of the medical curriculum. It concludes with a discussion of the theories of formation of coral reefs and islands, and an interesting note on the mythology and folk-lore of coral, entitled the Early Trade in Black and Red Coral. The illustrations, both photographs and diagrams, are many and beautiful, and the presentation is pleasing.

JOURNALS.

BRITISH JOURNAL OF EXPERIMENTAL PATHOLOGY. Vol. V., No. 6. December, 1924.—Percival Hartley: The Effect of Radiation on the Production of Specific Antibodies. The author concludes, from the results of experiments described, that exposure to radiation is without effect on the content of diphtheria antitoxin and typhoid agglutinin of the serum of immunised animals. Repeated small bleedings at short intervals may be followed by an increase in typhoid agglutinins in immunised rabbits.—Arthur Dighton Stammers: (Edema in South African Cattle.—Argyll Campbell and Leonard Hill: The Effects of Light upon Leucocytes and Blood-vessels in the Mesentery of the Living Animal. A simple method for investigation of the biological action of light is described, the determining factor being the production of capillary stasis in the mesentery of the frog. Further evidence is submitted that light has an important effect upon leucocytes. The endothelial cell of the vessel-wall appears to be involved.—S. L. Baker, F. Dickens, and E. C. Dodds: The Distribution of Insulin in Human and other Animal Tissues, with a Description of a Micro-method for the Estimation of Insulin in Tissues. The insulin content of some of the organs

of the ox, pig, sheep, horse, and cat has been worked out. The insulin content per kilogramme of the kidneys and spleen has been found to be roughly the same as that of the pancreas in the human subject. The insulin content of the organs of a person dying in diabetic coma was found to be quite appreciable. No delayed action was found with any of the preparations, whether from the pancreas or elsewhere. Active material, indistinguishable from insulin, was prepared from potatoes and onions.—J. C. G. Ledingham: The Reaction of the Skin to Vaccinia Virus. The vaccinal lesion has been studied histologically in its various manifestations. The lesion is essentially of the order of an acute infective granuloma in which the reticulo-endothelial system is primarily and dominantly involved. There is no evidence that vaccinia virus possesses an elective affinity for epiblastic tissue. Evidence is afforded that precisely similar tissue responses occur when the virus is introduced into tissues remote from epiblast. In contra-distinction to vaccinia, anti-epidermal serum when introduced intradermally produced an early and definite toxic action on epiblastic elements of skin.—F. W. Twort, T. H. Ayling, and C. C. Okell and H. J. Parish also contribute articles, and a brief sympathetic memoir of the late Sir William Bayliss is included. There are eight plates, four in colour, all admirably reproduced, but arranged in a decorative style more appropriate to a less scientific periodical.

BRITISH JOURNAL OF CHILDREN'S DISEASES, Vol. XXI., October-December, 1924.—Dr. Thomas Brushfield contributes his Cambridge M.D. thesis on mongolism based on 177 cases admitted to the Fountain Mental Hospital from 1914 to 1924, and accompanied by 18 excellent photographs illustrating the characteristic features of the condition. He points out that mongols, like other varieties of aments, can be divided into idiots, imbeciles, and feeble-minded, the degree of amentia being in proportion to the number of mongolian characters. The differential diagnosis between the mongol and the cretin is set forth in tabular form. As regards the prognosis, Dr. Brushfield lays stress on the following points: (1) the large number of deaths connected with inflammation of the mucous membranes; (2) the high incidence of congenital malformation of the heart; (3) the lack of response to any therapeutic measures; (4) the general clumsiness of the body and limbs which prevent a mongol taking part in the healthy movements normal to a child. The average age at death was 7 years among 24 males and 6 years among 20 females. A study of 42 older mongols in other hospitals had convinced Dr. Brushfield of the following facts: (1) they had all grown more or less; (2) they were all much fatter; (3) they had all deteriorated mentally.—In a paper entitled an Investigation of 50 Cases of Mongolian Imbecility from the Out-patient Department, Hospital for Sick Children, Great Ormond-street, Dr. Dora M. Berry comes to the conclusion that there is very little evidence to support the pre-war theory that mongolism is due to the mother reaching the end of the child-bearing period, as over a half of the cases were first and second children. On the other hand, much evidence was obtained that the father was sexually defunct, as in two-thirds of the cases he had served in the army or navy, and in nearly half he had suffered from shell-shock, while the mothers were young and healthy.—In a paper on the Home Care and Treatment of Physically Defective Infants and Young Children, Dr. John Thomson discusses the home treatment of the blind, the deaf, and those who are crippled or invalids from other causes, emphasising the importance of preventing them being self-centred, discontented, and dependent through lack of a proper training in infancy.—In their paper on Post-Operative Acidosis in Children, Dr. Philip C. Jeans and Dr. Kenneth H. Tallerman record their observations on 14 cases. The blood and urine were examined before and after operation, and those substances which might be causative factors

were estimated. The writers found the lowering of the alkali reserve to be due in but small measure to acetone bodies or to lactic acid accumulation, nor was phosphate retention the cause of acidosis. They conclude that some as yet unidentified factor is largely responsible for the lowered alkali reserve. Qualitative tests for acetone bodies in the urine gave but a poor indication of the degree of acidosis present, if compared to the variation in alkali reserve.—In a paper on Infective Hepatitis with Cirrhosis, Dr. Robert Hutchison and Dr. Donald Paterson describe a case of subacute liver atrophy with consequent cirrhosis and commencing regeneration of liver cells.—Dr. Edgar F. Cyriax contributes a paper on the Antero-Posterior Tilt of the Pelvis: Its Variations and Their Clinical Significance in Children, in which he emphasises the importance of recognising and correcting abnormal pelvic tilts in children, as the presence of this tilt means alteration of position and angle both relatively and absolutely of some or all of the abdominal organs.—The abstracts from current literature are devoted to dermatology and syphilis.

Reports and Analytical Records.

SCUROFORME.

(LABORATOIRE DES PRODUITS "USINES DU RHÔNE," 21, RUE JEAN GOUJON, PARIS; DICK, COATES AND CO., 41, GREAT TOWER-STREET, LONDON, E.C. 3.)

Scuroforme has been recently introduced as a useful local anæsthetic. Chemically, it is said to be para-aminobenzoate of normal butyl. It is a yellowish powder, almost insoluble in water, though soluble in alcohol and to a slightly less extent in olive oil and in vaseline. The fact that it is almost insoluble in water limits its action to the part where it is applied and prevents its absorption into the bloodstream, so that the manufacturers claim that it is practically free from toxicity. Certainly in those cases in which we have received reports concerning its use there have been no signs of toxic symptoms. Applied to a mucous membrane it soon manifests its anæsthetic effect, as can be shown by its application to the tongue or conjunctiva; and the anæsthesia is not preceded or followed by any sign of irritation.

On the unbroken skin it has no action, but where the skin has been deprived of its epithelium the drug produces a very definite effect, so that it may be usefully applied to painful ulcers, wounds, and burns. In the present state of our knowledge of the drug it might be advisable to be cautious in its use in a very extensive burn. In the dressing of these lesions of the skin the moisture of the affected part is first removed, and then a pad of cotton-wool impregnated with an oily solution of Scuroforme is placed on it for two or three minutes, and in most cases it will then be found that the part has been anæsthetised. The deeper the source of the pain the longer the drug will take to act. It can be mixed with other powders and dusted on to the affected part, or insufflated into a cavity, such as the nose. A lactinated powder may be used in nasal affections. Ointments are also of value either on the skin or applied to one of the openings of the body. Pastilles are manufactured for the treatment of painful pharyngitis and stomatitis; they are made with chocolate and so are pleasant to take. For gastritis, ulcer, and other painful conditions of the stomach Scuroforme tablets may be used; they are compounded with calcium carbonate. A solution in oil can be used in ulcerative stomatitis.

It can be employed as a local anæsthetic to the gums in dentistry, and, with all these indications, must be considered a useful drug.

PREMIDO.

(GEORGE HAMLETT AND SONS, LTD., WINSFORD, CHESHIRE.)

Premido or iodised salt has been prepared in response to a demand from districts in which goitre is prevalent.

It is not distinguishable from ordinary table salt either in appearance or flavour, while its iodine content has been found useful in certain cases of thyroid insufficiency and obesity. Other and larger claims are made for Premido salt, such as an action in cases of arterio-sclerosis, but the benefits in this direction following the ingestion of microscopic doses of iodine have not, as far as we know, received endorsement. The presence of iodine, however, might clearly be of use when the salt is used for a gargle or nasal douche.

SALVITÆ.

(AMERICAN APOTHECARIES' COMPANY, ASTORIA, U.S.A.; MR. LIONEL COOPER, 14, HENRIETTA-STREET, COVENT GARDEN, LONDON, W.C. 2.)

This preparation runs along familiar lines in its claims to alleviate disorders arising from nutrition, as will be indicated by its formula. Each tablespoonful of the powder contains 5 gr. lacto-citrate lithium, sodium, and strontium; 1½ gr. citrated caffeine; the remainder of the tablespoonful is made up of magnesium sulphate, sodium sulphate, sodium forma-benzoate, lacto-phosphate of calcium, and sodium with quinine, in an effervescent form. The dose, which is from one to four tablespoons, has been regulated by clinical experience, in accordance with the particular perversion of nutrition or sluggishness of excretion which is in question. It is stated to be especially useful in cases of chronic constipation where the passage of hard faecal masses is attended with straining. But all medical men will see by the formula that many pathological conditions might be benefited by one or other of the ingredients, the results of the treatment being watched for response.

CEREAL MEAL.

(THE CEREAL MEAL CORPORATION, ST. LOUIS, MO., U.S.A.; S. GUTTERMAN AND CO., LTD., 35 AND 36, ALDERMANBURY, LONDON, E.C. 2.)

We have examined a sample of a 14-oz. tin of this breakfast food which has been prepared with a view to promote intestinal activity along natural lines. Cereal meal is a combination of the cereal with flax-seed, agar-agar, and bran, and the design of the preparation is sufficiently indicated by its composition, the linseed oil acting as a temporary lubricant. The argument of the manufacturers that, as each of the ingredients has its use in the treatment of constipation, the combination must necessarily be satisfactory in results, would hardly stand rigid cross-examination, for such a general and probable rule does not apply universally, but it would appear that in the United States Cereal Meal has been found to act up to the claims made for it, and it is fair to anticipate the good results. The medical profession can make personal trial of Cereal Meal, for a sample tin will be sent free of charge to interested practitioners who apply for it.

KI-UMA.

(BATH: 6, MILSOM-STREET.)

This ointment, which is recommended for painful and swollen joints, neuritis, and sciatica, is the product of the berry of an African tree, of which pharmacology appears to know nothing, but the juice of the berry is combined with salicylates whose value in such circumstances is widely testified to. A statement that the ointment is free from the usual odour of winter-green suggests the presence in the preparation of methyl salicylate which has been reported upon in responsible quarters as an efficient application for local rheumatic pains. The specimen sent to us for a report is accompanied by an unfortunate article suggesting that here we have a botanical secret wrested from a tree known only to Ju-Ju men, but this little story is balanced by good opinions quoted from well-known medical men who have appended their names (not for publication) to their opinions of Ki-uma.

THE LANCET.

LONDON: SATURDAY, JANUARY 10, 1925.

"ADDITIONAL BENEFITS."

SOME readers will have learned with surprise from an article on Ophthalmic Benefit for Members of Approved Societies, which appeared in our last issue, that an "optical benefit" exists under the National Health Insurance Act. Not only does it exist, but it appears to be one of the most popular of the "additional benefits" for which the surpluses of the approved societies at the last valuation were made available. We are informed that in 1924 a sum of nearly £40,000 was available for its provision, and that in one very large society the claims have been as high as 500 a week. In spite of the rule that insured persons should only be able to get their spectacles on the production of a prescription from a qualified practitioner or from a hospital, it has been found impracticable to insist on this condition, and many of the approved societies send their members frankly direct to an optician. There is even a "refraction hospital" in London staffed by opticians. Stimulated presumably by the need for self-defence, the ophthalmologists have taken steps to form a panel of experts to meet the great demand which has been revealed. There was, no doubt, a very real danger of the benefit being provided by inexperienced persons, or at any rate by persons who, however expert, had limitations of training carrying obvious risks; so that in the interest of the insured population it is gratifying to know that professional committees have been formed to put the scheme on a proper basis, and to ensure that the services rendered should be of a high standard. Herein lies a lesson of deep import for the rest of the medical profession. Co-operation of specialists of all kinds is essential for the provision of many forms of additional benefits. The provision of consultant and expert services is clearly the next step in the development of the national insurance scheme.

Legislation will be required in order to provide specialist services out of insurance funds, and no fresh legislation is likely to be forthcoming until the report of the Royal Commission, now sitting, has been presented to and discussed in Parliament. It is understood that this Commission will consider schemes for future developments when they have completed their review of the insurance scheme as it now stands. From evidence already given it seems clear that there is a great demand for additional services on the part of approved societies and their members. Indeed, in some respects the laymen are showing greater eagerness than the medical profession, although there is a growing demand on the part of insurance practitioners for help in the diagnosis and treatment of their patients. Laboratory facilities are in some measure provided by hospitals and public health authorities, but access to an expert opinion from pathologist, bacteriologist, or laryngologist, to say nothing of the general consultant, has yet to be established. It is clearly necessary for the various specialists and practitioners interested in expert services to formulate schemes for their provision, as a right, to insured persons. Some professional body must be prepared to present the views of the consultants and specialists to the Commission, and we feel sure that the Ministry

of Health would welcome a statement of the extent of the need for such services and the probable cost of the new provision. General principles are set out in the joint memorandum drawn up by a committee of the British Medical Association, of which a summary appears on p. 95. This is a document showing evidence of fair-mindedness and reasoned judgment for which the medical profession as a whole has reason to be deeply grateful to Dr. R. A. BOLAM and those over whose deliberations he presided. In it is worthily maintained the tradition, a little obscured in the early days of the Insurance Acts, that medicine has primarily in view the health and happiness of the community which it serves.

The specialist sections must now be stirring in the expectation of developments. Time is short, and it is imperative that all professional bodies who are interested in the question of these additional provisions should be ready with practical suggestions. When the demand comes from the public—as come it will when the Commission reports—the medical profession cannot afford to be dilatory in showing its willingness and ability to supply that demand.

THE PROTECTION OF HONEST DRUGGING.

FOR practical purposes British law is powerless to prevent any person from procuring any drug or making any mixture, whether potent or without any therapeutical activity whatever, so long as it does not contain a scheduled poison; advertising such a mixture in any decent terms as a cure for any disease or ailment, recommending it by bogus testimonials and the quoted opinions and facsimile signatures of fictitious physicians, and selling it under any name he chooses, on the payment of a small stamp duty, are also open to the proprietor of such a mixture, and he can ask for it any price which he can persuade a credulous public to pay. The situation so described had long been the subject of outspoken criticism in these columns and in those of medical contemporaries, before our legislators found it so intolerable, that ten years ago a Select Committee was appointed to report to the House of Commons on the matter. This Committee made a series of recommendations, which if given effect to would put an end once and for all to grave scandals. Their report appeared in August, 1914, at a moment when the whole thought and energy of the country were being devoted to even sterner matters; and the position is substantially unchanged up to the present moment. It is true that in 1920 Dr. ADDISON, while in office as the first Minister of Health, introduced a Proprietary Medicines Bill, the provisions of which confirmed in general the recommendations of the Select Committee; but this Bill, after the second reading in the House of Lords, was unable to secure further consideration in Parliament. A year ago Mr. NEVILLE CHAMBERLAIN, then Minister of Health for the first time, was unable to undertake to introduce legislation on the subject during that Parliamentary session. Mr. CHAMBERLAIN is again Minister of Health, with a period, we may believe, of settled office before him, and we reiterate the conviction, expressed in 1914, that when at some future date the legislature can return to the performance of its normal functions, one of the most useful tasks lying to its hand should be to embody in an Act of Parliament the recommendations of the 1914 Select Committee.

What these recommendations are can hardly generally be known, for the Report has long been out of print and can only be read in reference libraries. But it is available in our own columns. It was printed word for word in our issues of Sept. 5th and

12th, 1914, and we make it more accessible to-day in a Special Supplement which appears in the present issue. There appears to be little or no difference of opinion in regard to the means required to suppress abuses which are admitted on all hands to exist, and whose results are open to the clearest proof. The Report of the Select Committee was unanimous, and all political parties in 1920 were prepared to give it favourable hearing. Respectable manufacturers and those responsible for the better sorts of proprietary and patent remedies, as set out in the classification of the Report, would welcome the protection from unfair competition which such a Bill, if it became law, would ensure; and the Association of British Proprietaries has recently given the public assurance through its secretary, not only that the Bill was not dropped owing to any request from the manufacturers themselves, but that the measure would suit the manufacturers as well as the public. In face of such arguments, the question need hardly be asked: Does patent medicine advertising need cleaning up? And that question was, in fact, answered in the affirmative by prominent advertisers themselves at a recent meeting of the London Publicity Club, a notice of which appeared in our columns last November.¹ The patent medicine business, Sir WILLIAM VENO said, in this debate, laid itself open to criticism because men with fraudulent intentions were attracted to it, and he was personally sorry that the Bill introduced four years ago had not become law. The manufacturers, he added, had studied it clause by clause, and found nothing objectionable in it. With such a mass of evidence in favour of reform we trust that the medical profession will join the public in insisting upon the early attention of Parliament to the whole matter. Big interests are involved, a fact which has already been used as a plea for delay. We can quite understand that in spite of its high objects a measure against quackery will meet with opponents. The sooner, however, a start is made the sooner will the cause of national health prevail. Delay is useful when the ground of a campaign has to be prepared, but on the subject of quackery no longer time for reflection is needed.

The passage of a Proprietary Medicines Bill would not at once bring the millennium in the matter of drugs and drug-taking, but it would enable effective reform to be initiated from within the pharmaceutical profession itself. There have recently been encouraging signs of a desire for such a reform. Restriction in the sale and distribution of remedies has been cheerfully accepted both by the druggists and the public in cases where medicine has been able to state with absolute positiveness that such and such a drug will cure, and that to withhold the drug or substitute any other is to endanger the patient's recovery. No preparations of salvarsan or its similars can be placed upon the market without the sanction of the Ministry of Health under very stringent conditions of inspection, and, as time goes on, no doubt our knowledge of other remedies will become so exact that they will ask and deserve a similar degree of protection. Many examples on the borderland will readily occur to the mind. Since 1920 the discovery of insulin has made it essential to place diabetes on the schedule of touch-me-nots, and it is unlikely that an amendment for its exclusion, which was set down four years ago, would be persevered with. But the time has not yet come when it is for the well-being of medicine to exclude initiative or definitely to

prohibit competition in the production of remedies for multitudes of common ailments. We have as yet no *arbor vitæ* conveniently bearing vital principles ready to hand for all purposes. But from every side assurance has been given that the proposed measure to deal with proprietary medicines would help to clean up a valuable industry and curtail licence without infringing a just liberty. We appeal to the Minister of Health to take an early opportunity of ensuring the passage of such a measure through Parliament.

THE PATHOLOGY OF PYORRHOEA.

SOME time ago an announcement appeared in the lay press to the effect that Dr. HAROLD BOX, of Toronto, had discovered some new facts in the ætiology and pathology of pyorrhœa which were likely to revolutionise our conceptions of this disease. His work is now available in the latest bulletin¹ of the Canadian Dental Research Foundation. While it may not merit the highly coloured eulogies in the lay press, it is of considerable importance and sheds valuable light on the pathology of periodontitis and pyorrhœa. In this country the view which has received most support is that pyorrhœa commences as an inflammation of the gum margin (gingivitis) which gradually extends down the roots of the teeth and attacks the periodontal membrane. This latter becomes stripped from the cement, leading to the formation of a pocket lined with infected granulation tissue. Concurrently with these changes there is absorption of alveolar bone and usually at some stage a discharge of pus. The bony support of the teeth becomes gradually destroyed and the teeth become progressively loosened and may eventually fall out. According to this view, the lesion is always an open one, a progressive ulceration from the surface of the gum extending into the periodontal membrane. Opinions differ as to the ætiology, but there has been much support for the views of J. F. COLYER and J. G. TURNER that the essential factor is the stagnation of food which leads to bacterial invasion of the tissues. At the same time there has been a considerable amount of speculation as to the possibility of some general cause which initiates or, at least, predisposes to these local changes. Dr. BOX has investigated exhaustively the patho-histology of the gum and periodontal membrane and his account differs materially from current conceptions. He gives an elaborate classification of the various types of gingivitis, recognising no fewer than 13 forms, a refinement which is, perhaps, excessive and confuses rather than helps. He notes that in subacute gingivitis a typical feature is the proliferation of the epithelium which normally lines the trough between the free edge of the gum and the neck of the tooth. This epithelium tends to invade the periodontal membrane and plays an important part in causing a separation of the membrane from the root.

Perhaps the most striking feature of Dr. BOX's work is his description of a form of periodontitis which he terms "rarefying pericementitis fibrosa," and which he regards as a pathological entity which has hitherto escaped notice. This is a chronic and progressive lesion of the periodontal membrane which leads to rarefaction of the alveolar bone. It manifests itself by the formation of a new tissue in the periodontal membrane which changes the normal arrangement of this tissue and gradually replaces the normal bone. It commences by a proliferation of the endothelial cells lining the blood-vessels which may occlude their lumen. Endothelial cells appear around the vessels accompanied by occasional lymphocytes, plasma cells, and fibroblasts. Dr. BOX regards the process as a low grade of inflammation, but does not think that the new tissue should be looked upon as typical granulation tissue, for there is no characteristic

¹ THE LANCET, 1924, ii., 1146.

¹ Studies in Periodontal Pathology. H. K. BOX. Bulletin 7, Canadian Dental Research Foundation. May, 1924.

development of new capillaries. This tissue appears as irregular nodular masses in the periodontal membrane which destroy the regular arrangement of fibres and lead to a loosening of the tooth. A concomitant rarefaction of bone is set up by extension of the new tissue which stimulates the activity of the osteoclasts. HOWSHIP'S lacunæ are formed and the fibrous tissue creeps into the recesses and often extends in finger-like formation along the blood-vessels, thus causing an internal rarefaction of bone. A further phase of the process is the replacement of bone by an osteoid tissue, especially on the surface and in the Haversian canals. Dr. Box notes as significant that the superficial changes in the gum may be very slight and may bear no proportionate relation to the changes occurring in the periodontal membrane. He considers that rarefying pericementitis fibrosa occurs typically in teeth which over-function through an abnormal occlusal strain due to some deviation from their normal position in the arch. He notes, too, a striking resemblance between this process and osteitis fibrosa, and suggests that rarefying pericementitis fibrosa must be studied in parallel relation with similar changes in other bones.

Dr. Box uses the term periodontitis in a somewhat different sense from most authorities. Instead of considering it as primarily an inflammation of the periodontal membrane, he uses it to comprise an inflammation of the gingivæ, periodontal membrane, and alveolar bone. These three structures are the tissue components of the supporting structures of the teeth. He employs the term "periodontium" to include all three. He excludes alveolar abscess and granulomata from the category of periodontitis because in these conditions the gingivæ are not involved. There is an elaborate classification of the various forms of periodontitis recognised by Dr. Box. The condition which is somewhat loosely called "pyorrhoea" is, according to Dr. Box, a complex one, and he recognises several types. There is a simple form in which the lesion commences as an ulceration of the gum margin which extends inwards and gradually destroys the periodontal membrane and bone and is often characterised by the presence of pus. This process is centripetal and corresponds to the account of the pathology of pyorrhoea as given typically by J. G. TURNER and J. F. COLYER. The second class of periodontitis which Dr. Box calls "chronic complex periodontitis," is quite different. It is produced by the coalescence of two distinct lesions, rarefying pericementitis fibrosa and infective periodontitis. The latter condition consists of three phases: chronic gingivitis, chronic pericementitis, and infective osteitis (rarefying and productive). These appear in this order. According to Dr. Box, the majority of the cases of what is usually called pyorrhoea belong to the category of chronic complex periodontitis.

An interesting feature of the chronic gingivitis as described by Dr. Box is the part played by the epithelium in the formation of a pocket. The epithelium which normally lines the gingival trough grows into the periodontal membrane and separates the fibres which are attached to the cement. He finds this to be a fairly constant feature, and notes that even when the pocket has extended to a considerable depth so that the cement is freely denuded, the surface of the soft tissue is usually lined by epithelium, and that surprisingly little ulcerated tissue is present. He considers that this indicates a defensive power of the cells which tends to reduce the lesion to a non-ulcerative type of inflammation. He admits that in some cases the fibres of the periodontal membrane may be destroyed by ulceration, but regards this as uncommon. Dr. Box considers that this has an important bearing on treatment and that theories regarding treatment should be based on the assumption that in practically all pockets the detached tissue sooner or later becomes covered with epithelium. The changes in the bone (infective osteitis), as described by Dr. Box, do not present any features different from those described by many other writers. While the classification of Dr. Box

helps to emphasise the different aspects of the lesions in pyorrhoea, it appears to be needlessly complex and over-elaborated.

Reduced to essentials, Dr. Box's conception of the pathology of pyorrhoea seems to be as follows. A few cases commence as a simple ulceration at the gum margin which extends into the periodontal membrane and strips it from the cement. By an extension of the ulcerative process the pocket thus formed gradually becomes deeper, and at the same time the alveolar bone undergoes a progressive absorption. In the majority of cases, however, the process is quite different. The disease is initiated by a regressive change in the periodontal membrane which is not preceded by ulceration of the gum margin. This change is characterised by the formation of fibrous tissue which replaces the orderly arrangement of the fibres in the membrane. The new tissue invades the bone and replaces it to a varying extent, thus leading to a loosening of the affected teeth. This condition (rarefying pericementitis fibrosa) must be regarded as the essential agency in bringing about the formation of a pocket with denudation of the cement, destruction of alveolar bone, and formation of pus—the condition which, clinically, we regard as pyorrhoea. While infection plays a part in the later stages in which ulceration occurs, Dr. Box does not consider that bacterial invasion is the primary factor. In his view the first cause is an over-functioning of the teeth due to a deviation from their normal arrangement which so strains the periodontal membrane as to initiate the development of rarefying pericementitis fibrosa.

It has usually been held that, when once the cement was denuded, reattachment of the periodontal membrane could not occur. From time to time statements have been made that reunion has occurred in treated cases, but the evidence was clinical and not very convincing. Dr. Box believes that it does occur and produces histological evidence to show it. If this be so, it is a very important point and confirmation from other workers would be welcome. In face of Dr. Box's microphotographs it is difficult to deny the possibility that this may occur, though under what conditions and to what extent is at present doubtful. Dr. Box notes that the new attachment differs from normal. The fibres run parallel with the surface of the cement instead of transverse, and it is evident that such a reattachment does not represent a complete anatomical and functional restitutio ad integrum, but only a limited though still valuable recovery.

Such is a brief outline of Dr. Box's views. In many respects they are novel and arresting, and are certain to arouse much interest among dentists. They certainly shed considerable light on the pathology of this important disease and, if confirmed by others, should give encouragement to the conservative treatment of pyorrhoea. A feature of Dr. Box's brochure, which it would be ungrateful to pass over without mention, is the large number of very beautiful microphotographs both of normal and abnormal conditions of the periodontal tissues with which the monograph is lavishly illustrated. It is certainly the completest study of the "periodontium" which has yet been made, and has laid all workers in dental anatomy and pathology under a debt to Dr. Box and to the Canadian Research Foundation which has made this valuable publication possible.

THE Hunterian Oration will be delivered by Sir D'Arcy Power in the theatre of the Royal College of Surgeons, Lincoln's Inn-fields, at 4 P.M. on Saturday, Feb. 14th, the anniversary of the birth of John Hunter. It will be illustrated by lantern slides made from a series of contemporary drawings showing John Hunter the Man and Martyr to Science. It is noteworthy that in its long history the Oration has never before been given by father and son. Sir D'Arcy Power's father, Mr. Henry Power, a valued member of the staff of THE LANCET for over 30 years, was Hunterian Orator in 1889.

Annotations.

"Ne quid nimis."

THE NEW YEAR HONOURS.

THE list of New Year Honours was not free for official publication until the issue of THE LANCET last week was entirely in the printer's hands, when a brief note was all that could be published. We take this opportunity of congratulating Mr. John Campbell, Dr. Thomas Morison Legge, Mr. H. J. Waring, Prof. Frederick Gowland Hopkins, Mr. Henry J. F. Simson, Dr. Frederic Truby King and Major-General Robert C. Macwatt, upon the honour of knighthood. Dr. Truby King is the Director of the Child Welfare Division of the Department of Health, New Zealand, and General Macwatt is the Director-General of the Indian Medical Service. We are also delighted to congratulate Miss Louisa Aldrich-Blake, Dean of the London School of Medicine for Women, on her appointment as Dame Commander of the Order of the British Empire.

Other honours include the following: Companionships of the Bath are conferred upon Major-General Sebert Francis St. Davids Green, C.B.E., K.H.P., late R.A.M.C., Director of Medical Services of the Western Command in India, and upon Major-General Harold John Kinahan Bamfield, D.S.O., K.H.P., I.M.S., Deputy-Director of Medical Services of the Eastern Command of India; and a Companionship of St. Michael and St. George upon Dr. Wilberforce John James Arnold, colonial surgeon at St. Helena. Companionships of the Order of the Indian Empire have been conferred upon Colonel Clement Henry Bensley, I.M.S., Inspector-General of Civil Hospitals and Prisons, Assam; Lieut.-Colonel Edward Cecil Gordon Maddock, I.M.S., late civil surgeon, Poona; and Lieut.-Colonel Joseph Charles Stolke Vaughan, I.M.S. (ret.), superintendent of the Radium Institute at Ranchi, Bihar and Orissa. The Kaiser-i-Hind Medal of the First Class has been awarded to Dr. H. T. Holland, medical officer, Church Missionary Society, Baluchistan; Dr. Sorab Cowasji Hormusji, first assistant health officer at Bombay; and Dr. (Mrs.) Grant Stait, medical missionary to the American Baptist Mission at Udayagiri, Nellore District, Madras.

Both the new appointments to the Order of Merit have scientific interest: Sir Ernest Rutherford, the Cavendish Professor of Experimental Physics and Director of the Laboratory at Cambridge, has made researches, notably in radio-activity, whose bearing upon the medicine of the future may be guessed at rather than calculated. Sir James George Frazer, in "The Golden Bough," has opened up paths of thought for medicine alike on the anthropological and philosophical side, which have already led to valuable conclusions and reservations.

THE ARTICULAR COMPLICATIONS OF MUMPS.

IN a recent Paris thesis Dr. Prosper Maisondieu remarks that the occurrence of articular complications in mumps was first described by Rilliet in 1850. It is probable that owing to its mild character mumps rheumatism often escapes notice. As a rule it does not develop until convalescence, and does not prevent the patient pursuing his usual occupation. The rarity of the complication is shown by the fact that during an epidemic of mumps in Paris in 1923-24, out of 984 cases admitted to the Claude Bernard Hospital only four developed rheumatism. Dr. Maisondieu has also collected from children's hospitals or isolation departments statistics of 350 other cases of mumps, only two of which had this complication, so that out of a total of 1334 cases of mumps there were only six examples of rheumatism, or 0.44 per cent. The date of its appearance varies according to different observers, but with few exceptions rheumatism is a

late manifestation of mumps, sometimes not occurring until 15, 16, or even 29 days after disappearance of the parotid swelling. In such cases, however, the association of the articular complication with mumps is indicated by the persistence of other complications such as orchitis or a subfebrile temperature. Mumps rheumatism seldom attacks several joints at once, but, as a rule, is monarticular at first, and later involves one joint after another. Not only are the joints proper invaded, but also the synovial sheaths and muscles in the neighbourhood. The principal symptom is pain, which varies alike in intensity and duration, and is most marked on movement of the affected joint. Redness and swelling are inconstant, though sometimes the effusion may present the appearance of hydrarthrosis. As a rule the temperature is not raised, or only to a slight degree. A few cases, however, have been recorded in which it rose to 102.2° or 104° F. The affection may last five or six weeks, owing to the invasion of several joints in succession or from interposition of a period of complete remission. Often, however, it is only of transient duration. Two distinct types of mumps rheumatism have been described. The first is an arthralgic form in which several joints are affected at the same time without any obvious reaction of the synovial membrane, while the second is a monarthritic form in which, in addition to severe pain, there are considerable redness, swelling, heat, and signs of articular effusion which may even advance to suppuration. As a rule, however, complete resolution takes place and no sequelæ result. The thesis contains the histories of 12 cases, six of which are original.

INFECTION SPREAD BY VAGRANTS.

WE have received a letter from Mr. J. Theodore Dodd, J.P., Barrister-at-Law, a well-known ex-guardian, pointing out the considerable danger during the present time of the spread of infectious disease by vagrants. The Ministry of Health have constantly drawn the attention of boards of guardians to this danger. But Mr. Dodd thinks that the survey¹ recently issued by the Ministry of the accommodation in the country for the casual poor shows that a number of these boards do not exercise the necessary precautions.

In confirmation of his opinion Mr. Dodd cites some of the figures given in the survey. The number of casual wards included was 490. Of these, 64, or about 15 per cent., had no satisfactory baths or no bath at all. In only about half of the wards was a freshly washed towel provided for each casual. Mr. Dodd also draws attention to the statement in the survey that many boards of guardians are still disposed to regard nightshirts as a luxury. Yet the regulations as far back as 1882 require that the casual's clothes shall be taken from him and, if requisite, dried or disinfected, and that the guardians shall supply him with a night garment and return his own clothes in the morning. Mr. Dodd refers to a ward, not mentioned in the survey, in which there is no provision for cleaning the clothing of the casuals, but the clothes, wet or dry, dirty or clean, are put up in bundles in a cupboard. This particular ward was dirty and the nightclothes very dirty. As regards cleanliness, the survey states that 15, or about 3 per cent., of the wards were poor. In 93 cases the survey describes the general condition of the ward as bad. Mr. Dodd's proposal for a remedy is that the county council should ask each district council to instruct their medical officer of health or sanitary inspector to visit the wards in his district and report thereon. He thinks it is unlikely that the guardians would refuse to admit such officer or to reform any serious defect after the matter was made public. If, however, the guardians raised objections, it would be easy for the council, says Mr. Dodd, either (1) to appeal to the Ministry of Health to send a medical inspector, or

¹ Cmd. 2267. H.M. Stationery Office. 3d.

(2) to ask a resident J.P. to visit the ward in accordance with the Workhouses Act, 1790.

Whatever may be thought of Mr. Dodd's proposals, it seems obvious that these casual wards should not any longer be allowed to remain outside the jurisdiction of a competent public health authority. The survey, the results of which have just been published, was begun in September, 1923, and undertaken for the express purpose of the revision and codification of the regulations relating to the relief of the casual poor. The Ministry of Health may therefore reasonably be expected to act promptly on the information with which it has been provided. The survey shows that the casual wards in England and Wales have accommodation for some 14,000 casuats, and that the largest number provided for on any one night was 10,099. The margin of accommodation is, however, to a great extent illusory, as the numbers in any one district fluctuate so much. The Poor-law authorities appear to have acquired the duty of looking after vagrants by accident, as the regulation of houseless persons has generally been regarded as a police duty. There has been a great increase in casuats since 1919, but the figures have not yet reached those for the period 1907-1912.

THE HEALTH OF PALESTINE.

THE annual report of the Department of Health of the Government of Palestine for 1923 is summarised on another page. It is a report which can be read with real pleasure, for although the urgent need for economy entailed ruthless reduction of the estimates and rearrangement of the work, yet the results are better than those of any previous year. No doubt the careful training of the staff in former years has fitted them for larger responsibilities, and the lesson of epidemics has made the people fearful of letting public health work drop. Hence they took over some of the expense which the authorities were unable to find, while the religious communities, particularly the Jewish, carried out, on a charitable basis, work that would otherwise have lapsed. The chief medical triumph of the year is the decrease of malaria. In over 35,000 blood films examined there were found in 4000 benign tertian, in 900 malignant tertian, and in 100 quartan. The numbers reported¹ in 1922 were, for 30,000 films, 3374 benign, 2319 malignant, 61 quartan; this year the second half had only 2000 cases against 3000 in the first, an evidence, as everyone experienced in malaria will realise, of a greater reduction to come in 1924. Anopheles is now rarely found in towns, and in no large town was there a new case of malaria in 1923, except in Haifa, which is surrounded with marshes. In one large rural area of 200 square miles malarial attacks decreased by half. The menace of malaria was met by drainage, by mosquito-proofing wells and cisterns, and, in the open country, by leaving irrigated areas to dry from time to time, either by damming the streams and only letting them flow every five or ten days or by diverting water in turn from each of the irrigation channels of a group. The (Rockefeller) Malaria Survey Section provides plans for getting rid of malaria; the (Jewish) Malaria Research Unit controls the actual measures taken. Well-watered land can by wise measures be made healthy in a couple of years. Financial stringency led also during the year to extensive closing of hospitals, but here also in some cases municipalities stepped in and carried them on. While the Travelling Ophthalmic Hospital has ceased to run, school teachers are still being shown how to treat trachoma, and systematic courses were given in the Ophthalmic Hospital at Jerusalem to doctors and their helpers. Schools generally are being used to spread a knowledge of hygiene, and especially to induce people to seek early treatment when bitten by rabid animals. Palestine now makes its own anti-rabies vaccine, and 609 cases were treated in dispensaries through the country, with three failures. Other interesting points,

of which the report is full, may be noted briefly. There are no antivaccinators in Palestine, where the memory of devastating small-pox is still recent. Pilgrims, before they leave the country, are injected with T.A.B. and cholera vaccines, and Government seeks to save them from exploitation. The lepers—80 in number—are cared for by the Moravians, and most of the lunatics by the Jews. Villages are now scavenged and cleaned, some of them get piped water, and stone-built markets are replacing the deplorable hovels that were the only food shops. The improvement of the health of the country in the last five years is a happy aftermath of the war.

CUSTARD OF COMMERCE.

A RECENT issue of the *Medical Officer* contains a full account of the prosecution which took place last month at Durham arising out of a tin of "custard powder" bearing on its label the inscription "Foster Clarke's Cream Custard, of course, does not contain cream, but it does contain the secret, which is the despair of imitators, for producing the most delicious cream custard of exquisite flavour." Foster Clarke's cream custard was proved by analysis to consist of maize farina tinted and flavoured without any egg or milk whatever. The summons was against the retailer, not the manufacturers, under the Food and Drugs Act, 1875, and it was contended on behalf of the prosecution that the purchaser was entitled to expect to receive a custard of superior quality, that the basic ingredients of custard as shown by dictionaries and cookery books should be eggs and milk, and that these could have been added by the manufacturers, if desired, in powdered form. In their absence the article was not of the nature, substance, and quality demanded by the purchaser of cream custard. The evidence included that of the county analyst, who pointed to the inferior nutritive qualities of a so-called custard from which milk and eggs were excluded; of Dr. T. E. Hill, medical officer of health for the county of Durham, who was of opinion that cream custard should contain eggs and milk in some form, and that if they were absent there should be a statement to that effect on the label; and of Dr. H. Kerr, medical officer of health for Newcastle, who pointed to long custom and the practice of the medical profession as authority for eggs and milk being necessary ingredients of custard. As a medical superintendent of hospitals he should not dream of allowing a patient who was ordered custard to be given so-called custard made from the powders in question. He admitted in cross-examination that they were used in "tremendous quantities" and said that it was "unfortunate for the working classes that they should have offered as a custard what was not in fact a custard." Asked if with eggs and milk the cost would be greater, he said, "Yes, but why call it custard?" The managing director of the manufacturers was called for the defence, and said the word "powder" was omitted from the label for the sake of brevity, but was now added with a statement of the absence of eggs, and that the word cream expressed the consistency of the prepared article, as in such expressions as "toilet cream." Messrs. Foster Clarke had sold 200,000,000 packages in 15 years with only one complaint by the same prosecutor in 1920. Other witnesses had sold the powder without complaint. Addressing the bench for the defence, Mr. J. H. Compston, K.C., said that the absence of milk and egg was generally recognised by the public and that the dictionary meaning of the word "custard" had changed completely during recent years. The magistrates dismissed the summons, but refused to allow the defendants' costs.

It is matter for regret that in the absence of any definition by the legislature, an old-established word associated with an article of diet in common use should be employed in selling an article of far less nutritive value than that to which quite recent generations of our ancestors were accustomed when they ate custard. Those cooks who make their own custards use milk and eggs to this day, but no doubt are a diminishing body. They may also be slightly

¹ Dr. Jehoasch Gordon, Arch. Schiffs- u. Trop.-Hygiene, 1923, xxviii., 391.

more economical than Mrs. Glasse, who, in her famous "Art of Cookery," published at the end of the eighteenth century, gives as the proportions for a "plain custard" a quart of new milk sweetened to taste to eight eggs with half their whites omitted. She would add a little nutmeg and rose-water for flavouring. For a richer "almond custard," she prescribes a pint of cream, a quarter of a pound of almonds "beaten fine," two spoonfuls of rose-water, the yolks of four eggs, and sugar to taste. What Mrs. Glasse would have said to the description of coloured maize flour as "cream custard" can hardly be imagined.

SUNLIGHT.

THE Sunlight League was founded in May of last year, and it has recently published the first number of "Sunlight: a Journal of Light and Truth."¹ In an editorial foreword it is stated that the purpose of this new publication is "to work for the restoration of the light of the sun to all who live in cities, and to affirm the principles and applications of light for health, and in the prevention and cure of disease." In the pages which follow there are congratulatory messages from eminent men and women, and articles by experts dealing with the various problems which affect the Sunlight League. Sir Oliver Lodge writes on Sunlight for Health; Dr. Leonard Hill emphasises the importance of the skin through which the sun, wind, and rain can do so much to influence the activities of the body; Mrs. M. A. Cloudesley Brereton deals with the question of the modern woman's dress and health, and she advocates in a restrained yet emphatic manner the value of "clothes light in weight, warm enough to conserve the body's natural heat but porous enough to let in light and air, loose enough to allow of free active movement." The Smokeless City is the title of an interesting article by E. D. Simon and Marion Fitzgerald, and the question of housing and sunlight is dealt with by A. Trystan Edwards under the title of the Sun-Trap House. The smoke nuisance is attacked from several points of view, and it is interesting to learn from an article on this subject by Colonel Thwaites that in 1307 a man was executed in England for burning "sea-cole" to the detriment of his neighbour's health! What has actually been achieved in the way of "sun cures" in this country is described under the title of Days in the Sun: the Story of Ken Wood, and Miss Margaret McMillan shows both what tremendous damage absence of sunlight does to the children of our big cities, and also what encouraging possibilities lie ahead of us in an extension of the open-air nursery school system. A page has been reserved for book-reviews, but there is strangely no reference either to the publishers or to the prices of the books mentioned. Further matter includes an account of the objects of the Sunlight League, and an appeal for "Lamps" by Miss McMillan, and this brings us rather to the heart of the problem which is well presented in an article entitled Artificial Sunlight, by Dr. C. W. Saleeby, reprinted in this journal from the *New Statesman*. "The inevitable has happened," he says. We have had to attack the problem of sunlight and health not by abolishing smoke and letting the sun shine down upon the rich and poor alike, but by the introduction of artificial sunlight—"the makers are racing one another to produce as many lamps as possible." While this seems all to the good, judging by the results of the treatment of rickets, for example, by artificial sunlight, there are certain dangers to be faced in the use of this method, and Dr. Hill wisely states that "the carrying out of artificial light treatment requires to be controlled by the medical profession, for great harm may be done by the injudicious use of powerful sources of ultra-violet rays." This new journal has objects with which all those working for the health of the community must be in sympathy, but there is no indication as to whether it is to be a monthly or a quarterly publication,

and it rather looks as if future numbers will contain a reiteration of the same material. This will not matter as long as it has the desired effect of driving home to the public the great importance of sunlight as our best "preventive medicine"; the fear is that the health authorities will be tempted to buy artificial daylight lamps rather than deal with the real problem of smoke abatement.

THE TRAGEDY OF LEWIS.

LAST year the report of the school medical officer for the Lewis division of Ross-shire made pitiful reading, and this year again Dr. Agatha E. Miller has a dreary tale to tell of hardship and privation, and the struggle for life of a sturdy seafaring race large of stature, strong of muscle, born with a heritage of health to be found nowhere else on these islands, rapidly deteriorating and slowly dying out from poverty and its privations. Dr. Miller reports whole schools of these children with hardly an unsound tooth between them, and she has never seen a case of rickets on the island. But the story of deterioration is told clearly enough in the tables of comparative weights for the children of Lewis and of the mainland of Ross-shire who come of similar stock. There is a loss of weight among the Lewis children at all ages during school life, and there is noticeable, too, a deterioration since 1921, which was the last fairly normal year as far as weather and economic conditions are concerned. These Ross-shire children "have inherited," writes Dr. Miller, "a fine physique second to none, but in Lewis we have to stand by and see their steady deterioration, robbed of the fish they depend on for their staple food, dependent only on the very limited amount of land developed on the island and sinking into ever deeper poverty." Comparisons of heights and weights of English children with those of these Lewis children are valueless. They belong to a different race, almost the tallest in Europe, and are comparable with children of the taller Northern races of Europe. Their height, as may be seen from the table which we reproduce, is second only to that of Swedish children, who are tallest of all.

Comparative Average Height Table—in Centimetres.

14	146.8	148.8 152.4	—	148.2	155.6	152.2

What is going to happen to these people, or rather what is to be done about the problem they set us? They are entirely dependent on the natural produce of the land and of the sea. Their clothing is made of homespun wool or tweed. The majority of the cotton garments worn are made out of old flour-bags, and Dr. Miller says flour-bags make strong garments, costing only 3d. each. They are literally being starved out of existence, and although at the end of 1923 there were signs of somewhat better prospects, "the school year had opened with increasing rain, cold, and wind, wet fuel, a damaged harvest, much of it blown away. The minimum of straw and hay for the cattle meant the minimum of milk, and it is difficult to exaggerate the importance of milk when fish, the staple diet, had become so scarce. There was only a small quantity

¹ Sunlight. Vol. I., No. 1. December, 1924. The Sunlight League, 37, Russell-square, W.C. 1s.

of diseased potatoes available from the harvest." "I never saw in school," Dr. Miller adds, "so many children who were not fit to be there, either tempted out by the provision of a midday meal or forced out for want of a sick certificate. . . . It is not recommended that gymnastics be taught indiscriminately to Lewis country children. Many of the children are fit to take part and would greatly benefit; on the other hand, many have too far to walk to school, and are tired. The exertion of the school day takes a good deal out of under-nourished children." Various relief funds came to the help of the islanders last year, giving a midday meal and clothing to necessitous children, and offers of help have been renewed this year, but the trouble, though immediately relieved by such kindly measures, calls for deeper remedy. They are a proud people, too, and require careful handling, but even so, it should not be past the wit of man to devise some practical and acceptable means of helping them to help themselves. We must not forget that Lewis responded as one man to the call to arms at the very beginning of the late war. Many of the men were killed, and in her report Dr. Miller draws attention to the fact that the best-fed and best-clothed children are the children of war widows.

PAROXYSMAL TACHYCARDIA.

Paroxysmal tachycardia is often regarded as a functional disorder of the heart. Dr. John Parkinson described it as the best example of such at the Ottawa meeting last year¹ and was taken to task for doing so by Dr. A. Graham-Stewart and others in our own columns. Can a "functional" disease kill? was the burden of this correspondence. A valuable paper on Paroxysmal Tachycardia, with Special Reference to Prognosis, by Dr. F. A. Willius and Dr. Arlie R. Barnes, of the Mayo Clinic, Rochester, Minnesota, affords the opportunity of returning to the subject. The authors give the results of observations on a series of 102 cases which were seen in the cardiac department of the Mayo Clinic between 1914 and 1923.² The authors define simple paroxysmal tachycardia as a condition in which, from time to time, the normal mechanism is interrupted by a series of rapid irregular beats varying in rate between 100 and 200 each minute, the series starting and ending abruptly. The 102 cases were divided into four groups as follows: (1) 36 cases of nodal tachycardia which were subdivided into five cases in which the P.-R. interval was diminished, 28 cases in which the P.-R. interval was zero, and 3 cases in which there was an R.-P. interval; (2) 7 cases of auricular tachycardia; (3) 6 cases of ventricular tachycardia; and (4) 53 cases of auricular flutter. All the cases were carefully examined, and were all verified by electrocardiographic tracings taken during the attacks. The clinical picture of the condition is well known, the most important characteristic being its sudden onset and abrupt cessation. In the symptomatology, the authors give prominence to vertigo, which was associated with the attacks in 18 cases, 15 of which were male patients and 3 female. Eleven of the patients were over 49 years of age and the incidence of arterio-sclerosis and hypertension was high. Stress is laid on the strong probability of cerebral arterio-sclerosis acting as a determining factor in the occurrence of vertigo associated with paroxysmal tachycardia—a point that has hitherto received little attention—and it is urged that a history of attacks of tachycardia should be carefully excluded in dealing with an elderly patient who complains of vertigo, especially if evidences of arterio-sclerosis are present. Besides vertigo there were other manifestations of cerebral anaemia. Five patients had syncope during attacks, two were delirious, one had epileptiform seizures, three had spells of unconsciousness in their paroxysms, and three said that everything became black before their eyes. One patient complained of numbness and

another became aphasic during a paroxysm. In 40 cases in which the date of onset was noted, the average time during which the attacks had occurred was 12 years. In three cases the attacks had recurred over a period of 40 years or more, the longest period being 43 years.

In considering prognosis, the after-histories of 84 cases of the 102 seen in the clinic were obtained. This large number is noteworthy, as unless the percentage of after-histories is high, they are of little prognostic value. From the data furnished by the circularised questionnaire, the authors conclude that attacks of paroxysmal tachycardia do not appear to have contributed much to cardiac failure or to incapacity. The death-rates were high in cases of paroxysmal tachycardia associated with aortic and coronary disease (57 per cent.) and with endocarditis (46 per cent.). The final conclusion is that the estimation of the prognosis of paroxysmal tachycardia depends very largely on the estimation of the type and degree of the underlying cardiac damage. This conclusion is a reasonable one which might command general acceptance.

GLANDULAR THERAPY.

ECONOMISTS are fond of talking about the laws of supply and demand and, within certain limits, an increased demand produces an increased supply. During the last few years the tremendous increase in glandular therapy has led to a demand for preparations of the various ductless glands, and the huge supply which has resulted shows no signs of the shortage which economically one would be led to expect when dealing with animal products. It has been said that if the parathyroid glands of all the animals in the world were added together they would not equal the quantity in the market, but this is probably an exaggerated statement which in any case would be difficult to prove. If we except insulin, pituitary gland extracts probably represent the most successful and satisfactory of the preparations of the ductless glands.

Now the anterior lobe of the human pituitary in an adult weighs on an average about one-third of a gramme. The usual weight given for the whole gland is 0.5 g., and the anterior lobe forms about two-thirds of this. The usual preparations of the anterior lobe contain five grains, "representing this weight of fresh glandular substance," or almost exactly the weight of the whole anterior lobe in the human subject. The quotation given above is taken from a pamphlet recently issued by Oxo, Ltd., on the pituitary gland, and a picture in this pamphlet of a bottle containing 100 tablets, each consisting of 5 gr. of the pituitary of the ox, makes it of interest to know the size and weight of the bovine pituitary gland. It is perhaps to dispel the distrustful suggestions contained in the above remarks that the pamphlet includes a picture of the pituitary gland of man compared with that of the common hump-backed whale. The endocrine sceptic would probably prefer to see the gland of an ox used for comparison purposes, and perhaps in future editions of these interesting booklets in the "Oxoid" series, dealing with the various glandular products of this reputable firm, pictures of the ductless glands of the bovine species will be introduced. The guarantee of "quality, potency, uniformity, and reliability" of these prepara-

¹ THE LANCET, 1924, ii., 481.

² Boston Medical and Surgical Journal, 1924, exci., 666.

tions is unreservedly accepted by most medical men; it remains to be seen how the suspicions of the sceptic may best be quieted.

BICENTENARY OF GUY'S HOSPITAL.

THE 200th anniversary of the opening of Guy's Hospital, on Jan. 6th, 1725, ten days after the founder's death, was commemorated on Tuesday by a service in Southwark Cathedral. The Prince of Wales, President of the hospital, was present, and Dr. Burge, Bishop of Oxford, one of the governors, preached. It was a simple, short, and admirably arranged service, consisting of hymns, a psalm, the collect of St. Luke, a thanksgiving "for our founder and benefactors," prayers for "our doctors and nurses," "our patients," and "past members of the hospital." The lesson, from Ecclesiasticus xxxviii., "Honour a physician with the honour due unto him," was read by the Bishop of Southwark. The crowded congregation included many distinguished medical men and six former matrons of Guy's Hospital.

THE CONTROL OF MEAT.

THE Departmental Committee on Meat Inspection has reason to be gratified by the early recognition which its recommendations are receiving. Regulations referring to meat inspection were issued some months ago and a supplementary series¹ has now been issued conferring additional powers on local authorities in respect of slaughter-houses and slaughtering, meat marking, and control of sale of meat products. A considerable weakness in meat control has always been that the rural districts lacked some of the powers of urban authorities. The present regulations are reinforced by the Rural District Councils (Slaughter-houses) Order² of 1924, under which the Minister of Health directs that the provisions relating to the regulation of slaughter-houses shall be enforced throughout the rural districts. Meat marking has now become an acknowledged and approved procedure, but very rightly the Minister retains control of the process by requiring that authorities shall have an adequate and competent staff to ensure that the inspection prior to marking can be properly carried out. As pointed out by Dr. W. J. Howarth in his Milroy Lectures,³ a system of meat marking places the butcher in a better position, for the carcase having been officially examined, the butcher can only be held responsible subsequently for what is known as "condition." If on cutting up the carcase signs of disease are discovered, then the discovery is regarded as one which the butcher can hardly be expected to have observed. There is no reference to this in the regulations, but in the accompanying letter it is suggested that "if in any case evidence of disease is found (in officially marked meat) the fact that the meat had been previously examined and passed by a competent authority should normally make it unnecessary to contemplate the institution of legal proceedings against the person offering it for sale." Provision is made in the regulations for notification to the local authority of intention to slaughter, but no such notice is necessary where it is the regular practice to slaughter at fixed times, and notification of this arrangement has already been made to the authority. In view of the fact that the slaughter-house is the proper place in which to examine carcasses, provision is made for the retention of internal organs with certain provisos. The blowing of carcasses by the breath is prohibited and restrictions are placed on the use to which a slaughter-house can be put. Further regulations controlling the sale of meat on stalls, in shops and stores, and the transport and handling of meat have also been framed. These are reasonably comprehensive and if intelligently observed will leave few grounds for complaint, though in certain

instances it would not be difficult to make suggestions which might be regarded as an improvement although of necessity more restrictive. In London the method of handling meat has long been severely criticised both by individuals and in the public press, and the Corporation of London since 1915 have pressed the Ministry to frame regulations which would enable them and other metropolitan and provincial authorities to deal with this important matter. The new regulations will have a far-reaching effect in another way. Control of sale of food products being now accepted in principle, other regulations of an associated character may be expected to follow.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CIV.—TREATMENT OF CRETINISM.

CRETINISM, according to the classification in general use, is divided into two varieties—endemic, which is common in the Alps and Himalayas, and sporadic, which is scattered all over the world. A classification based on external factors such as geographical distribution must of necessity be unsatisfactory, but there is justification for the temporary use of this particular division, in that the sporadic variety usually presents the clinical picture which might be expected from simple loss or diminution of thyroid secretion in the individual himself, whereas the endemic form appears to be due to a multiplicity of factors (more or less hypothetical), such as hypo- and dys-thyroidism in the mother, hypo- and dys-thyroidism in the individual, and pathogenicity of one or other of the germ cells. Thus the endemic cretin shows a far greater diversity of symptoms. In some the brain is severely affected with a nearly normal bony skeleton; in others dwarfism is extreme with comparatively little mental defect; and the development of the sexual organs is very variable.

The causal distinction just made helps to remind us that it is only in sporadic cases that we can expect to get a striking result through treatment of the individual. In the endemic form efforts must be directed mainly towards prophylaxis by treatment of the parents and especially of the mother. Probably cases which, although occurring sporadically, resist treatment, are in their essential nature of the endemic variety.

Attempts have been made to distinguish between sporadic cretinism and infantile (or juvenile) myxoedema. The distinction is an artificial one. The age at first onset of the symptoms varies in different cases, but there is no break in the series to enable us to distinguish between those in which the thyroid is functionless at birth and those in which the function is lost at a later period. There is by no means always a history of acute illness preceding the onset of the cretinism in the latter case. The treatment is identical. It has been stated that, the child being protected by the maternal secretions, the cretinoid condition is never patent at birth, symptoms being longer delayed in breast-fed infants. This statement is too strong. M. B. Gordon found that out of 113 cases in which the age of onset was noted symptoms were present at birth in 13, and my own experience agrees with this.

Cretins and Mongols.—In spite of the many excellent descriptions in text-books it is still necessary to stress the radical difference between cretinism and Mongolian imbecility, the more so that certain scientific workers have assumed that the latter is partly at any rate due to lack of thyroid secretion. The prognathous face of the cretin is just the opposite of the over-flattened face of the Mongol, and there is not a scrap of evidence in favour of there being any close relationship between the two diseases. The use of thyroid

¹ Public Health (Meat) Regulations, 1924. Statutory Rules and Orders, 1924. No. 1432. H.M. Stationery Office. 2d.

² Circular 552. H.M. Stationery Office. 1d.

³ THE LANCET, 1917, ii., 147, 225, 335.

extract in the latter condition is a waste of time and raises false hopes in the minds of the parents.

Active Principle of the Thyroid.—It is not yet settled whether the secretion of the thyroid gland contains only one biologically active chemical substance or more than one. A number of substances which have been isolated from the gland have had their actions tested on animals. Of these, the chief are iodothyrene (E. Baumann), iodothyroglobulin (A. Oswald), thyreoglandol (Hoffmann-La Roche), and thyroxine (E. C. Kendall). All these have physiological action, and it is interesting to note that one of the most active (thyreoglandol) contains practically no iodine, although the function of the gland itself shows a general correspondence to its iodine content. We are not yet in a position to say that any one of these substances or any mixture of them acts in exactly the same way as the internal secretion of the thyroid gland, and therefore it is still advisable to rely on the fresh *liquor thyroidei* or on preparations of the dried gland substance for the purposes of administration. Judging by clinical results the products of the best firms are remarkably constant if not kept for more than a month or two. They should be standardised to contain at least 0.05 per cent. iodine.

Susceptibility and Dosage.

One of the most remarkable things to be noticed during the administration of the drug is the varying susceptibility of different patients to its toxic effect. In one child, whom I treated, 1 gr. a day at the age of 2 years produced toxic effects; in another 9 gr. a day produced very little effect, either remedial or toxic, but improvement began immediately when the dose was increased to 12 gr., and this dose was continued for years with excellent results. Gordon, in a collection of 280 cases from the United States and Canada, found that in one case thyroditis was produced by $\frac{1}{2}$ gr. daily, and that in another case 45 gr. were given with impunity. It is a very general experience that it is much easier to overdose a cretinous than a non-cretinous child. This is the opposite of what one would expect on the supposition that the thyroid extract is merely supplying a deficiency, and shows that even in apparently simple cases of endocrine deficiency there is a complicated mechanism involved. The more caution has to be exercised because effects, whether remedial or toxic, are apt to lag behind the increases of dosage, so that there may be a cumulative effect. When once toxic symptoms have appeared it is not enough to reduce the dose slightly; susceptibility seems to be heightened and the dose has to be dropped by a considerable amount. Thus it is important to avoid all toxic effects or progress may be much delayed. On the other hand, it is possible to be too timid, and fail to affect the cretinism sufficiently by using too small doses. A very small beginning ($\frac{1}{4}$ gr. daily), with regular weekly increments and careful inspection, will make for safety, and at the same time ensure adequate dosage. The minimum adequate dose is the rule, but it must be remembered that it is possible to be satisfied with a medium progress when a little more boldness would produce much better results. Certain cases where the margin between the therapeutic and toxic doses is small are very difficult to treat. It is said that arsenic is of value in such cases.

The symptoms of an overdose are restlessness, insomnia, screaming, sweating, diarrhoea, vomiting, tachycardia, wasting, and exhaustion. It is not difficult to detect these symptoms in an early stage, and especially so if a weekly record of the weight be kept. After the first two or three weeks (while the thickened subcutaneous substance is being absorbed), the cretin under treatment should gain in weight regularly, and a loss in weight should at once raise the suspicion of overdosage. When this occurs all thyroid should be stopped for a week or longer, and then reinstated at half the previous amount. In two cases I have known epileptic convulsions begin

during treatment, and cease again when the dose was diminished.

It is quite unnecessary to operate on the umbilical hernia which is so frequently present. It almost invariably disappears rapidly, *pari passu*, with the other symptoms. Aperients, such as calomel, combined with moderate doses of sodium bicarbonate, are sometimes of value in the early stages of treatment.

The operation of *grafting* has been tried from time to time, but no great claims can yet be made for it. It is generally agreed that the human gland should be used, though S. Voronoff has claimed success with that of an anthropoid ape. It is important to distinguish between temporary and permanent success, the former being not uncommon.

Factors Determining Ultimate Results.

The ultimate result after prolonged treatment with thyroid extract is variable, the greatest variation being in the amount of mental defect left. In my own experience there has been variation from complete idiocy to normality. What is the most important factor in determining the result? It has been stated, and it would at first sight appear plausible, that the most important factor is the age at which treatment is begun, combined with the intensity of the cretinism. My observations do not support this view. The following are two instances of contrast:—

A cretin girl was brought up for the first time at the age of 13; her size was that of an average baby of 2 years old; she was carried in her mother's arms. By the time she was 18 she was entered at a special school for the physically defective, where she learnt easy reading, writing, and arithmetic.

Contrast her case with that of a cretin boy on whom treatment was first commenced at the age of 2 years and 10 months. The torpor and all the distinctive features of cretinism rapidly disappeared, but he was transformed into a chattering idiot unable either to walk or talk.

Again, about ten years ago, within a short period of time two cretins each of the age of 5½ months were brought up. They appeared of about the same grade and responded equally to treatment, which has been kept up ever since. The one, a girl, is now taking her place in a class with girls of her own age, and by the Binet tests her intelligence quotient is 98. The other, a boy, after being in the infants' class for about two years, has been discharged as ineducable.

It may be that some of the endemic causal factors are present in the more unsatisfactory cases, but there appears to be also a general correspondence between the final mental result and the age at which the first symptoms were noticed. Thus the idiot mentioned above is the son of an intelligent mother who has had a normal child both before and since his birth. Her story is quite explicit that he lay like a log from the day of his birth, and never uttered a sound until treatment was begun. This correspondence between age of onset and final mentality runs through all my cases, and, if not a mere coincidence, would receive a ready explanation from consideration of the time of myelination of the cortical fibres, the harmful effect of thyroid deprivation being more permanent on the immature nerve tissue.

Where thyroid treatment only unmasks an idiot we are faced with the question as to whether it is worth while. Probably most parents would prefer King Log, and it would be merciful to let the patient relapse into his previous condition.

A. E. NAISH, M.B., B.Ch. Camb.,
F.R.C.P. Lond.,

Lecturer on Medicine, University of Sheffield;
Physician, Sheffield Royal Hospital.

THE LATE DR. E. C. MCCARTHY.—One of the best-known medical men in Stalybridge, Eugene Charles McCarthy, M.B., Ch.B. Vict., died on Dec. 26th. On graduation at Victoria University, Manchester, in 1892 he obtained honours in the Final Examination with distinction in obstetrics and gynaecology. For many years he had been in active practice in Stalybridge, but owing to ill-health he retired some years ago. He was school medical officer during the war and for some time afterwards. He was appointed a justice of the peace in 1895, and took an active part in the municipal affairs of the town.

Special Articles.

CONCERNING THE TWO TYPES OF SMALL-POX

AND THE ADMINISTRATIVE METHODS APPLICABLE
TO THEM.

BY R. W. JAMESON, M.R.C.S. ENG., D.P.H. CAMB.

It is venturesome to attempt to add anything to this subject after the masterly report on alastrim by Prof. Ricardo Jorge. But as there is in this country a grave need for the reorganisation of our small-pox administrative procedure, and as I have been a medical officer of health, have had experience of "amaas" in South Africa, was in 1923 in charge of the Gloucester Small-pox Hospital, and more recently in administrative charge of a small-pox outbreak in Ashington, Northumberland, and between those appointments saw something of the Willesden patients, my facts and tentative conclusions may be of use in eliciting the views of others.

Nomenclature.

I consider that to call classical small-pox, small-pox, and the non-fatal variety mild small-pox, alastrim, amaas, &c., even para-variola, is misleading. I would call them variola major and variola minor, and in the vernacular, serious small-pox and weak small-pox. This allows one administratively to call an outbreak variola or small-pox, leaving the necessary subdivision till such time as a typical case allows one to label the epidemic variola major or variola minor. This is to take up a medical position which the lay public can understand and appreciate.

Definition of Variola Major and Minor.—With regard to variola major, I need not attempt to improve on the text-book descriptions of classical small-pox. Variola minor is a disease which in an isolated case is usually indistinguishable from a mild case of variola major, but is characterised by being non-fatal, save in the presence of some more serious condition either of disease—e.g., cerebral hæmorrhage—or of the extremes of age—e.g., an infant of 6 weeks. It is unfortunate that at the present time the Registrar-General has confused the issue by calling the four deaths with small-pox at Gloucester small-pox, whereas they all come under the heading of persons with small-pox, together with a more serious condition, either of disease or period of life. The Registrar's rule for statistical purposes is that small-pox being mentioned on a certificate the other causes may be disregarded. This was and is substantially correct for variola major, but in the case of variola minor this rule is a source of error; and nowadays in this country investigation of all cases of death in persons with small-pox is necessary. Further, to differentiate variola major and variola minor, a weaker vaccinal barrier will completely protect the individual from variola minor than is necessary for protection from variola major. I am of opinion that four marks in infancy are absolutely protective for at least 12 years, and revaccination for 20 years. The quoted experience of Mr. Gouzien (THE LANCET, Dec. 27th, p. 1367) is an isolated one, and failing other evidence, from my own observations I hold his facts may bear some other interpretation. It is also to be remembered that prior to Prof. Jorge's paper last October, alastrim in the medical literature was an ill-defined entity, and some accounts of it read more like variola major than variola minor, and in others it seemed confused with varicella. It may be well to state here that variola minor and varicella are not mutually protective, as I have seen each followed by the other after only a few weeks' interval.

To come now to the 800 hospital cases at Gloucester and Ashington. I can omit the clinical picture, since

it would be mere repetition; among the cases adequately vaccinated in infancy the youngest was 13 years 9 months, there were three between 18 and 20, the others were all over 20 years, the total being 90.

Infectivity.

At Ashington, to obtain some indication as to the incidence of the disease on those exposed to infection, I took all the cases for two months, and found they came from 30 houses. Excluding the last five houses, as more cases might develop in them, I tabulated the inhabitants of the first 25 houses with the following result, which I quote from my report to the urban district council.

There were 168 persons resident in the 25 houses; of these persons 85 were unvaccinated and 83 had been vaccinated. Of the 85 unvaccinated 6 were successfully vaccinated after exposure to infection. The 168 persons may be grouped as follows: (1) Seventy-nine unvaccinated persons; of these 47 caught the disease and 32 escaped. (2) Six protected by vaccination after exposure to infection; these all escaped the disease. (3) Seventy-four persons of all ages who had been vaccinated in infancy only; of these 17 were under 20 years of age, and all escaped; of the remaining 57, all being over 20 years of age, 13 caught small-pox and 44 escaped. (4) Nine persons vaccinated in the army—that is within 10 years of exposure—all escaped.

From these figures the unvaccinated's chance of catching the disease was 3 in 5, while for the vaccinated in infancy only, and of over 20 years of age, the chance of catching the disease was less than 1 in 4. Those vaccinated within 20 years of the epidemic escaped altogether, as did the 6 vaccinated after exposure to infection.

Although the majority of the contacts who developed the disease caught it from the first case, four of the contacts who escaped infection from the first case subsequently caught it from the second case in the house; while two others developed the disease so long after the first case (39 days) that they presumably were infected outside their own house. Escaping infection once does not insure a person against catching the disease if again exposed to it.

The administrative fact of importance is that of the contacts, less than 1 in 4 of the unvaccinated, and none of those vaccinated in infancy only, would accept vaccination even though they had been exposed to infection. It is not an unnatural position for these individuals to take up, for the epidemic in a great majority of cases has been very mild, while vaccination at its best is not a pleasant experience. But communally it means that the epidemic cannot be brought to an end by protecting by vaccination persons liable to develop the disease, because they refuse to be so protected; and the only method available is that of removing infectious cases whenever detected, and as this cannot be done until a rash has developed, one can by this means only diminish the risk of infection—not abolish it. It is therefore impossible to say for certain when the epidemic will end.

From my other records it was clear that, as a rule, the infection was from neighbour to neighbour, and not from colliery, school, or other occupation. I have not been able to find any house records for other epidemics, but contrast the above with Willesden where the epidemic was confined to one house. The first case, source not known, was an unvaccinated child of 3 years, who had a very mild attack of small-pox. Every member of this household went down with small-pox, three died of hæmorrhagic small-pox; therefore the strain for all was variola major. The other six cases and the original case I saw during convalescence, and all save one were indistinguishable clinically from my Gloucester cases, but the remaining case, without the hæmorrhagic deaths, would, in my opinion, have established the strain as variola major, for it was a child of 12, with adequate marks of infant vaccination, and yet with a well-marked rash, making it quite impossible, in my mind, that the infection could be variola minor.

The Willesden household is an isolated example, but compare its infectivity with variola minor, where many escape: A gives it to B, C escaping, to be later infected by B. Willesden is an example of how easily one might err if the two types are designated mild and severe. It is also an example of how early in an epidemic the diagnostic case of variola major may show itself. Again, variola minor has crept about the Midlands for the last six years, and as my

figures indicate among a population very indifferently protected and largely unchecked, save by the isolation of cases. While there has been little variola major of recent years, and it has been very energetically treated and stamped out, yet surely it does show greater infectivity than variola minor. This is mere surmise without facts; one hopes the hazarded statement may elicit the facts as to the infectivity of variola major from some repository of that knowledge.

Vaccination.

If we were governed by a medical autocracy doubtless we should all be vaccinated and revaccinated sufficiently frequently to make a small-pox epidemic an impossibility in this country. But in fact we are a democracy, and therefore with the prevalence of variola minor there is bound to be a continuous diminution in the number of vaccinations done.

Vaccination where there is no Epidemic.—Administratively this consists only of the so-called compulsory vaccination of infants, which is more exactly described as the free vaccination of the infants of non-objecting parents. Here, where the object is to guard the infant from an improbable event at an uncertain future date, the more marks the better, as the effect lasts longer. But if general vaccination in non-epidemic times must be advocated, then, surely, together with the offer of this gift of vaccination to his child, it is only reasonable that the parent should be told that after seven years the protection is not to be relied on as against serious small-pox.

In non-epidemic infant vaccination the effects of vaccination are twofold: (1) on the individual; (2) on the community of which he is a unit.

As regards the *Individual*.—The desirability of vaccination in non-epidemic times is for him dependent on two factors only—the severity of the vaccination and the magnitude of the risk insured against. Variola minor is so mild and its infectivity relatively so low that to defer the consideration of vaccination against it until an epidemic period is surely reasonable. Therefore the only insurable risk to consider is that of variola major, and this risk depends on the degree of probability of his being exposed to serious type infection during the period in which the vaccination, if done, would confer complete immunity, together with the further period in which the remaining partial vaccinal protection would lessen his chances of death or disfigurement should he be exposed to and contract the disease.

Now I submit that the insurable risk for young children, that is their chance of exposure to severe type small-pox infection, has become in England so infinitesimal that one need no longer advocate that all babies born in England in non-epidemic times should shortly after arrival pay the premium of being vaccinated. Of course, in areas with a bad and recurrent variola major history one should advocate vaccination and revaccination, but those areas require to be investigated as to their sanitary organisation, housing, vaccinal condition, type of population, geographical position, and so on, in order to arrive at the cause of their peculiarity.

As regards the *Community*.—It is difficult to see the advantage to the community of vaccinating 40 per cent. of the babies born when 60 per cent. refuse vaccination, or even, if it were possible, the great advantage of reversing these figures. Further, variola minor has demonstrated in many parts of the country that we are now a relatively unprotected community, and that variola minor has no terrors for those who actually come in contact with it. Should not all our efforts be directed to vaccination when it is essential? And the conscientious objection form might be so altered that in non-epidemic times only those parents who declared that they had a conscientious desire for vaccination should have their babies vaccinated at public expense.

The figures for 1921 and 1923 are rather arresting. I have not seen those for 1922.

	1921.	1923.
Small-pox cases	336	2483
Deaths	5	7
Vaccinations	324,000	—
Vaccination deaths	8	12
From 1911 to 1920 small-pox mortality-rate 1 per million of population per annum.		

Epidemic Vaccination.—The present position is that no one is obliged to be vaccinated. Anyone may be vaccinated free, and many are; also the small-pox administration sends the names of all contacts to the public vaccinator that he may persuade them to accept his vaccination. The public vaccinator vaccinates many people because the epidemic is present, but one never learns what proportion of them were likely to come in contact with the infection. I therefore took a census of uninfected houses next door to houses from which cases had been removed, and found that of 158 persons none of the vaccinated had been revaccinated, that of the 50 unvaccinated three had been vaccinated as contacts; four had been vaccinated because of the presence of the epidemic—three of them because it was a condition of joining the Wembley excursion from a small-pox area, and the remaining one because the child wanted to wear the red ribbon badge. In the 25 infected houses already referred to there were no persons vaccinated only because of the presence of the epidemic. So far as these figures go they indicate that it is persons other than those most liable to infection that seek vaccination in the presence of an epidemic; and with variola minor this is what one would expect: that the class who read or otherwise learn about variola major would seek vaccination, while those who have experience of variola minor, or lacking any experience save that of vaccination, would not get vaccinated. And one can understand that a father of an unvaccinated family living amid unhygienic surroundings should be much perplexed as to what he ought to do should he see his neighbour A's children return obviously benefited by their stay in the country small-pox hospital, while his neighbour B's children are little bundles of misery with bad vaccination arms.

All vaccinations provided free by Government are of the same vaccine and of the same extent—four marks covering an area of half a square inch. In non-epidemic times it is reasonable that Government should get as great an acreage of scar tissue as possible for the money expended, in order that the effect produced may last as long as possible. But for the control of an epidemic in the present absence of legislative aid, to be acceptable, vaccination must be as little distasteful to the recipients as possible, while its protective effect need not last more than a few months. It is less distasteful than the Government method, if one only makes two small marks, less than a quarter square inch in total area, and disinfects them if the reaction be manifest on the fifth day with permanganate compresses until the scabs be black. But free vaccination has to be of the stereotyped Government form, and only in exceptional circumstances should an M.O.H. vaccinate a contact. In time of epidemic it is necessary that the administrator should also be in charge of vaccination, unhampered by the acreage regulations. If epidemics are to be checked it can in the case of variola minor only be in the early stage.

Procedure at the Start of an Epidemic.

I consider that in six weeks from the discovery of the first case of small-pox, given adequate powers, the epidemic should be at an end, or if not at an end should by then be diagnosable as being either variola major or variola minor; that it is necessary while in doubt to treat the epidemic as variola major; that the present absence of necessary powers is a possible source of danger to the community. The medical officer should have power to segregate, if necessary, any persons he considered contacts, and be allowed

to offer them the alternative of vaccination when he considered that safe, and to pay for wages lost by reason of vaccination if the individual elected to be vaccinated; this power to expire at the end of six weeks unless a designated official had not prior to that date declared the epidemic to be variola major. If he did so declare the power would remain operative after that date and until the end of the epidemic. This is not compulsory vaccination, but the offer of vaccination as an alternative to compulsory segregation.

Further, if the epidemic be declared variola major, vaccination should thereby become compulsory for all persons under 14 considered to be contacts by the medical authority, for one remembers how deadly variola major is to unvaccinated children. But, since we are a free country, I would allow this power to be withdrawn on a majority of the local council, consisting of at least half its members, so voting at a meeting called for this purpose, and on their own heads be the result of such action.

If variola minor be the epidemic which persists at the end of the six weeks, then it is necessary that the cases be notified to and seen by the medical authority, and due records kept for fear that variola major might be introduced into the area from outside, but it is not necessary to isolate them, though ill or inadequately housed persons should be admitted into the ordinary fever hospital as is done in the case of measles. No vaccination propaganda need be undertaken. Any contacts wishing vaccination should receive it free for the first six weeks of an epidemic, [and thereafter, if the disease be variola major,] cases would be sent to a small-pox hospital, and where necessary contacts to small-pox segregation quarters.

At present one cannot curtail the liberty of a tramp to wander, though one may think he is in the incubation stage of variola major, and to vaccinate anyone against their will by representing that they must be done is in law an assault.

Administrative Areas and Small-pox Hospitals.

The areas are far too small, the hospitals too many, and necessarily quite inadequate. They were arranged when only horse transportage was available, and before the invention of telephones. Small-pox administrative areas should be large—a combination of counties and county boroughs—administrative headquarters being preferably at a port. Six or eight such authorities should be sufficient for England and Wales. The administration, from the size of their area, would become conversant with small-pox. The minor authorities and their staffs would, as regards small-pox, be subordinate to the super authority. At present up and down the country medical officers of health gain small-pox experience to be for the future useless as their districts remain free. At present the small-pox hospitals, save in the large towns, each serve a population of about 75,000, that is, are practically always empty, and if there be an epidemic of any size are of no use. A large area authority would use motors and put hospitals capable of expansion from a central store at suitable points in their area.

There are a number of other matters both medical and non-medical that would be more efficiently and economically managed by them than is at present done by the smaller local authorities, and it may be that they might also be better fitted for some matters at present done by the central government.

Ministry of Health and Medical Research.

We come lastly to the supervisory administrative body, the Ministry of Health. They have allowed the present state of things to continue, and it is not their fault, for that which you have to administer and which has grown with your growth is not a thing you can yourself adequately criticise. The Ministry is a very efficient administrative body, its function is to administer, and this administration is based on ever-developing science. Any ordinary business has

an independent financial audit; the Treasury, I suppose, performs this function. When the administration is based on science it seems as though there should also be from time to time an independent scientific audit, and it seems to me that the Privy Council, from which in the great Sir John Simon's day all health reform emanated, should be responsible for this, and begin with the subject of small-pox. It merits consideration whether there is not something in this idea.

Summary.

1. *Nomenclature.*—I suggest one which can only be provisional until we know more of the nature of the virus concerned in variola major and variola minor respectively. One recognises this by using these two terms which take note of their clinically allied nature and their main difference, that of virulence, while they are calculated not to confuse the clinician as the terms mild and severe might do.

2. *Vaccination.*—Owing to the widespread objection to submit to vaccination and also to the fact that the immunity conferred by vaccination only lasts for a term of years, the present attempt to control small-pox by the wholesale vaccination of infants has failed. It is suggested that variola outbreaks would be better controlled if governmental vaccination effort were confined to treating outbreaks, and then used intensively, that in the presence of variola major one cannot have too much vaccination and therefore increased powers of compulsion are necessary for those times.

3. *Administration.*—That the areas of small-pox administration should be enlarged as making for efficiency and economy in dealing with the disease. That the efficiency of the machinery in use for dealing with this and other diseases would be enhanced if the Privy Council from time to time assessed the value of the procedure employed.

I have as far as possible eliminated all data and argument only supplementary to my main thesis and yet have written at considerable length in my attempt to deal with a very large subject.

If I have shown the need for further investigation of the subject under the general heads touched on, I have done what I set out to do.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Referees for National Health Insurance Work.

SOME nine years ago a scheme for the medical certification of insured persons was agreed on between the Irish National Health Insurance Commission and the Irish Medical Committee. In its main features this scheme has been in operation since Jan. 1st, 1916. One important part of the scheme, however, remained in abeyance up to the present—the provision of whole-time medical referees. The Irish Medical Committee had always pressed that there should be referees, and had even agreed that a proportion of the monies voted by Parliament to finance medical certification should be held back to pay for the referees. The monies were held back, but Government during the war years refused to sanction the appointment of referees. The Commission, then, in agreement with the approved societies, attempted to supply the lack of referees in another way. Small grants were made to the societies to enable them to pay for "second opinions" in such cases as they desired. The representatives of the medical profession protested that this arrangement was a breach of the bargain made between them and the Government, and that further it was unjust to the insured person, as it put in the position of referee a person chosen by and paid by the approved society. In spite of these protests the system has continued in force down to the present. It is understood, however, that the Government is no longer going to make these grants to the approved

societies, and the National Health Insurance Commission is about to appoint a small number of whole-time referees. An advertisement appeared last week in the daily press inviting applications from registered medical practitioners, with a knowledge of general practice, for three appointments as district medical referee.

The Question of Salary.

The appointment in each case is to be a whole-time temporary one, terminating on Dec. 31st, 1925. Salary will be at the rate of £600 a year, together with travelling and subsistence allowance. The Commission is to be congratulated on the step it is taking, but one fears that the conditions of appointment are not attractive enough to secure men of the proper experience and judgment. Few medical men in practice are likely to think of abandoning their practice for a temporary appointment. Moreover, £600 a year cannot be considered an adequate salary for a whole-time Government officer with considerable responsibility. Inspectors of the Ministry of Local Government are paid much more highly, in that the initial salary of £500 a year carries with it a bonus of between £200 and £300, and their duties are not exacting and do not demand any higher qualities of education and judgment. It will be unfortunate if the National Health Insurance Commission is not able to secure referees whose position in the profession will command respect both from practitioners and from approved societies. The appointments are to be made on the advice of a selection board set up by the Civil Service Commission.

No. 83 (Dublin) General Hospital, B.E.F.

On Jan. 3rd the members of the Dublin unit which served in 83 (Dublin) General Hospital at Boulogne for the year 1917-18 held their annual dinner in the Royal College of Surgeons. Colonel Sir William Taylor, K.B.E., who organised the unit, was in the chair, and 16 other members were present. There were three guests present, all of whom had been closely associated with the work of the hospital—namely, Colonel A. Fullerton, of Belfast, Vice-President of the Royal College of Surgeons in Ireland, and formerly consulting surgeon in the Boulogne area, and General R. H. Sawyer and Colonel Forrest, who were respectively D.D.M.S. and D.A.D.M.S. of the Boulogne area in 1917.

ROYAL MEDICAL BENEVOLENT FUND.

At the last meeting of the Committee 37 cases were considered and £547 10s. voted to 34 applicants. The following is a summary of the new cases relieved:—

M.R.C.S. Eng., 1896, aged 55, who, since demobilisation has worked at the Ministry of Pensions. Applicant is now unable to work owing to paralysis. He and his wife are now living on the charity of friends. His wife is quite willing to work but she has to look after the applicant. Voted £26 in 12 instalments.

M.D. Cantab., 1912, aged 71, who practised in Devonshire and London. Unable to regain his practice after the war and now, owing to old age and infirmities, can scarcely walk. His wife is able to work but applicant's health necessitates her constant attention. They are now dependent on friends. Voted £26 in 12 instalments and £10.

Widow, aged 58, of M.B. Glasg. who practised in Leeds and died in 1889. Applicant received £8 from maternity nursing but has been unable to work since August owing to trouble with her eyes. She is much worried as she is getting behind with her rent. She sub-lets one room for £12 per annum, and her rent and rates amount to £27 per annum. Voted £10.

Widow, aged 57, of L.S.A. Lond. who practised in Cornwall and died in 1923. Through illness applicant has had to give up her post as companion and is now entirely dependent on her daughter who earns 45s. a week. Voted £10.

Daughters of M.R.C.S. Eng. who practised in Berkshire and died in 1912. Their ages are 56 and 47. The eldest one nursed her father who was paralysed for 22 years and is not at all strong. The younger sister is a daily governess at £60 per annum. They receive help from their brother and brother-in-law. Voted £18 in 12 instalments and £12 in 12 instalments.

Subscriptions may be sent to the Hon. Treasurer, Sir Charters Symonds, K.B.E., at 11, Chandos-street, Cavendish-square, London, W. 1.

NATIONAL HEALTH INSURANCE.

DRAFT MEMORANDUM OF EVIDENCE TO BE SUBMITTED
TO THE ROYAL COMMISSION BY THE BRITISH
MEDICAL ASSOCIATION.

THE organisation of a national scheme of health insurance, so far as medical services are concerned, and the relationship of such a scheme to other services concerned with public health, form the subject of a Memorandum drawn up for the British Medical Association by a Committee over which Dr. R. A. Bolam presided, and accepted by the Council of the Association at its meeting on Dec. 17th, 1924. This draft Memorandum, which appears as a Supplement to the *British Medical Journal* of Jan. 3rd, 1925, is to be discussed at local medical meetings, whose replies will be considered by the Council on Feb. 5th with a view to the issue of a revised Memorandum on Feb. 18th, to be followed by further local meetings from Feb. 25th to March 5th. A representative meeting is to be summoned on March 12th, when after a final sitting of the Council on March 25th it is hoped that the printed evidence will be ready for submission to the Royal Commission on April 4th, so that any time after April 13th witnesses may be heard by it.

The draft Memorandum is divided into five sections, dealing with: (a) Persons to be provided for; (b) Extension of provision to be made; (c) Regulations and terms of service; (d) Administration; (e) Remuneration, with a preface of a more general character.

Prefatory Note on General Principles.

At the outset it is posited that the organisation of a national health insurance scheme is not necessarily (or even probably) the best means of utilising limited resources for the promotion of national health. An equal or better return would probably follow expenditure on such things as housing, town-planning, smoke abatement, pure milk-supply, regulation of alcohol, destruction of vermin, education, or the aiding of medical research. The principle of a scheme being accepted, regard should primarily be had to the maintenance of health and the prevention of disease. A scheme of national health insurance is defined as one through which in return for premiums or contributions participants are entitled to medical attendance and treatment together with certain ancillary services and also to cash payments (under certain conditions) during ill-health or disablement. The medical profession as such is concerned only with the former class of benefit and with the giving of such certificates and reports as may be required in connexion with the latter class.

A brief historical survey sets out how in 1913 the success of the system was jeopardised by antagonism, professional and lay, and by the lack of experience which led to unsatisfactory arrangements both for practice and administration. War and demobilisation followed, leaving barely three years of smooth and normal working.

Comparison of conditions before and since 1913 leaves no doubt in the medical mind that (a) many now receive medical attention who formerly did not; (b) the proportion of practitioners to population in densely populated areas has increased; (c) medical attention is superior to that of the old club practice; (d) illness is now coming under observation at an earlier stage; (e) there is a growing bias towards prevention; (f) clinical records are being provided which may be of service to research and public health; (g) co-operation among practitioners is encouraged; (h) the collective responsibility of the profession to the community in respect of all health matters is growing. If not wholly due to the insurance scheme, these advantages have been hastened and intensified by it.

The main difficulties of the present scheme are then set out: the strain on the practitioner in time

of widespread epidemic, the oppressive and even menacing nature of the quasi-judicial machinery with its volume of regulations. The mind of the individual doctor dealing with an individual patient may be diverted by fear of transgressing rules and regulations made for other purposes, with detriment to his work. The work of the medical service is rendered less (not more) efficient by multiplicity of departmental requirements.

The broad general principles regarded by the Association as fundamental are laid down as follows:—

(a) Medical provision should be available for those persons, and only for those persons, who would be unable to obtain it without the help of the insurance scheme.

(b) This provision should be, as far as possible, complete.

(c) Conditions under which medical attention is given should approximate as nearly as possible to those of private practice.

(d) Medical representatives should be closely associated with the administration of the scheme, and as far as questions of purely professional conduct and treatment are concerned, judgment should be in the hands of purely professional bodies.

(e) Remuneration should be on such a basis as (i.) would produce an income not less than that which corresponding responsibility and work should produce in comparable private practice, and (ii.) would not prejudice the continuous supply of the best type of practitioner.

Persons to be Provided For.

In general terms it is agreed that the scheme must include those economically dependent upon persons at present insured and other workers in like economic position, and that the same system might be extended to the actually destitute. Assuming the number of persons now insured to be 15,500,000, the number of dependants is estimated at one-and-a-half times as great, and the total number of persons to be insured at 38,750,000. There is no reason to suppose that the new entrants would be less costly to the scheme. Essential conditions of any extension would be the maintenance of infant welfare centres, adequate home nursing, a minimum of records and reports, and revision of the methods of dealing with complaints.

With a view to bringing the whole problem within measurable compass, it is suggested that:

(a) The classes of persons exempt from the scheme by reason of their contract of service including provisions giving benefits equal to those of the national scheme, should be extended to include others (e.g., bank and insurance clerks) not at present excluded.

(b) Persons with an unearned income of an amount per week not less than that prescribed for sickness benefit should be excluded.

(c) Any income limit (whether £250 a year or a lower amount) should be applied alike to the non-manual worker, the manual worker, and the voluntarily insured person.

(d) A lower income limit than that which is applied generally to insured persons should be necessary for the inclusion of dependants.

From the purely medical side the problem of provision of advice and treatment for the poor person not under contract of service, or for the necessitous person, is not regarded as specially difficult.

Extent of Provision to be Made.

Under the present scheme, medical advice and treatment provided is broadly such as can reasonably be expected from general practitioners as a class. The phrase "general practitioner advice and treatment," it is emphasised, does not indicate anything of inferior character. Such services are fully as important as scientific, and as highly skilled as those provided by other practitioners in more special lines of practice. The definition is mainly one of range. Under the auspices of local authorities there are now provided certain pathological facilities, treatment for tuber-

culosis and venereal disease, for infective fevers, for some conditions of children of school age, and provision for maternal and infant welfare. Individual approved societies contribute towards dental, ophthalmological, or institutional treatment. Provision for possible consultative advice through the regional medical officers has so far scarcely at all developed.

The Memorandum desires to make all such services and benefits an integral part of the insurance scheme, to bring them into proper relationship thereto so that they may be generally available, and to extend the provisions so as to include complete consultative and specialist advice and treatment, full laboratory facilities for clinical purposes, residential institutional treatment so far as is possible with a limited accommodation, dental advice and treatment, such ancillary help as can be given by nurses and masseurs, and an ambulance service—all this in addition to the existing general practitioner advice and treatment and the provision of necessary drugs and appliances.

All these benefits should, it is contended, be available equally to all insured persons alike, regardless of membership of any particular society. To avoid excessive demands they should be available only on the recommendation of the general practitioner, with some safeguarding against unreasonable or excessive use, and for composing differences of opinion between practitioner and patient or society, which might require an official referee. This general rule might be modified for the prescribing of necessary drugs or appliances by the consultant or specialist and for direct application by a patient to a dentist for dental treatment.

The medical personnel of the consultant or specialist service should consist of every registered medical practitioner willing to accept service and having satisfied the following criteria as to status:—

(a) That he has held hospital or other appointments affording special opportunities for acquiring special skill and experience of the kind required for the performance of the service rendered, and has had actual recent practice in performing the service rendered or services of a similar character; or

(b) That he has had special academic or post-graduate study of a subject which comprises the service rendered, and has had actual recent practice as aforesaid; or

(c) That he is generally recognised by other practitioners in the area as having special proficiency and experience in a subject which comprises the service rendered.

From the list of consultants and specialists so compiled, the practitioner, in agreement with his patient, would choose the individual considered most suitable for the particular case. In normal circumstances consultations would take place at the consultant's, the practitioner's, or the patient's house. Exceptional conditions might require the establishment of special premises or sometimes the use of a hospital out-patient department, when general practitioners not on the specialist list should be eligible as clinical assistants. Arrangement would be made for exchange of opinion and co-operation between practitioner and specialist, and provision made for insistence upon actual personal consultation where either considered it necessary, the primary responsibility of the general practitioner in charge being preserved in all cases. Existing clinics provided by local authorities would remain to function as centres for education in health matters, as places of appointment, as specialist clinics where consultations cannot be held elsewhere, and for persons not coming under the insurance scheme.

Complete provision of maternity care is regarded as an integral part of the medical service, whereby attendance at confinement and during the puerperal period together with special examination and supervision during pregnancy would be brought within the scope of the scheme. Such inclusion presumes an efficient service of registered midwives, provision for institutional treatment of serious cases, the liberty of the

practitioner to decline the work or to place his name upon the list for maternity purposes only. Remuneration would be on a special scale. Any insured woman would thus obtain medical examination (if desired) and supervision during pregnancy, attendance by a registered midwife during normal labour and the puerperal period (the ideal being both midwife and doctor), attendance of the practitioner when requested by the midwife under defined conditions, or when as the result of his examination he has declared his personal attendance to be necessary.

The clinical laboratory service standing as it does to gain by association with research work, is on a rather different footing. Routine investigations should not be allowed to interfere with the proper function of a University department. The work should be divided between a relatively small number of large central laboratories with special facilities and a larger number of small laboratories in which the tests would not involve the use of elaborate or exceptional apparatus. Highly trained pathologists being required it would be undesirable to restrict their activities to work under the insurance scheme. The Memorandum therefore regards it as desirable that laboratories should be established and maintained under other auspices with a suitable financial contribution from the insurance fund. Some approved clinical laboratories under private management might be recognised. Exchange of opinion between clinicians and laboratory should be arranged for.

Provision for resident institutional treatment envisages the use of existing voluntary hospitals of various types, of the hospitals for infectious disease, of the tuberculosis sanatoriums of local authorities, and of the present Poor-law hospitals, none of which could be restricted to persons under the insurance scheme, the cost of treatment to be defrayed in full out of the medical benefit funds, in accordance with the hospital policy of the Association.

A final recommendation under this heading suggests the abolition of restriction on appliances which may be ordered under the scheme; all appliances necessary for the sick person should be available, possibly in some cases on loan.

Regulations and Terms of Service.

The Memorandum lays down that the conditions of insurance practice should approximate as nearly as possible to those of private practice, and should preserve within wide limits professional customs and traditions. Some modification is entailed by the insurance principle and by the responsibilities incurred to State and administrative bodies. It is regarded as essential that any registered medical practitioner should be able to participate in the service as a right, and that the conditions of acceptance should be uncomplicated and un-onerous, in order that as large a number as possible should be willing to engage in the work. Questions of supposed neglect or lack of success or improper behaviour on the part of a doctor, and of unreasonable conduct on the part of a patient, may be solved very simply, the Memorandum suggests, by the exercise on both sides of complete freedom of choice, it being understood that no practitioner shall abandon his responsibility for an actually ill person until other attendance has been secured. Over and above this obvious solution of the whole question of complaints, the Memorandum takes no exception to a statement in general terms as to what constitutes reasonable conduct on the part of a patient or what in general are the duties which the doctor undertakes to perform.

Two requirements on the part of the patient, unnecessary in private practice, are laid down. An insured person should be required (1) to seek acceptance by a doctor before the occasion for medical treatment arises; (2) to claim treatment by the production of a medical card or otherwise at the first consultation. On the other side, the insurance practitioner should be liable to a penalty for (1)

wilfully charging a fee for any service undertaken as a part of his insurance service; (2) such general conduct as is held to be detrimental to the interests of the service. Statements made in records, reports, or certificates about a patient's condition, should, it is held, if honestly made, be regarded as matters of professional judgment not liable to complaint beyond that to which all practitioners are liable. Wilful failure to keep records or wilful false statement are excepted. Certain definite proposals are made in regard to official complaints: (1) that all complaints against a practitioner should, in the first instance, be sent to the chairman of the local medical committee and the chief administrative medical officer of the local authority; (2) that only such as cannot be settled by them should proceed further; (3) that questions of general conduct detrimental to the service should be reported upon in the first instance by the local medical committees; (4) that appeal to the courts should be possible not only on the ground of improper procedure, but also against a penalty out of proportion to the offence; (5) that in the case of proposed removal from the service the practitioner should have the right of appeal to a duly constituted central professional committee.

It is admitted that uniform regulations or terms of service are difficult of general application and the special conditions of rural and colliery areas are dealt with in appendices. Opinion is expressed that the standard of treatment at so-called medical aid institutes is not equal to that given by the service as a whole; that the great majority of medical men decline to take service under the conditions laid down for them, and that the need to the community of such institutes does not justify their being placed outside the general scheme of medical benefit.

Administration.

Unification of medical services contemplated in the Memorandum would involve the disappearance as such of insurance committees and the transfer of the health functions of the Poor-law guardians, although, of course, members and officers of these bodies would be indispensable for the work of the unified authority. Each such authority would have a chief administrative medical officer, no doubt in most cases the existing medical officer of health. A statutory local medical committee would take the place of both the existing panel committee and the existing local medical committee, with funds provided for administrative purposes. This committee would appoint representatives on the local health committee to conduct negotiations on behalf of the profession, to advise on professional matters, and to perform any other statutory duties imposed. This committee should have the right to present its view directly to the Ministry of Health and to the public.

Administration of the cash benefits, it is remarked, does not primarily concern the medical profession, but evidence of serious imperfection in the administration of approved societies, both in notifying the enrolment of insured persons and their suspension from medical benefit, continually comes before the notice of practitioners. The Memorandum points out, with admirable fairness, that the proportion of cases in which there is cause for complaint is no doubt small in relation to the total number of occasions on which complaint might have arisen. But the delay to notify members who have passed out of medical benefit is regarded as serious enough to form the object of a special statement. On the evidence of the Central Index Committee there were during a period of 18 months 503,000 persons whom doctors were liable to attend in respect of whom no contribution was forthcoming.

The Memorandum stresses the high importance with which medical certification is regarded by the medical profession. Any conclusions to the opposite effect drawn from examination of large numbers of medical certificates or from references to regional medical officers are due to misinterpretation or

misunderstanding. Bodies responsible for the administration of cash benefits certainly have a right to be consulted with regard to certification arrangements, and in the main, medical certification in relation to sickness benefit is remarkably well done. Certain alterations in the forms of certification would conduce to harmonious working. The phrase "incapable of work," the technical meaning of which has needed a pamphlet to set forth accurately, should be altered. Initial and final certificates might remain, but the intermediate certificate requires modification.

In the event of separation of the administration of medical benefit from that of cash benefits, many doctors, it is stated, believe that this administration is likely to be more satisfactory and sympathetic in the hands of certain classes of approved societies than in the hands of a large State organisation or committee of a local government authority. If approved societies are to continue, the following requirements are suggested. They should be: (1) of such a size as would constitute a properly insurable group; (2) of such a character as not to vitiate a uniform insurance scheme; (3) of a constitution so simple as not to put their members at a disadvantage; (4) obliged to classify all their members on a territorial basis; (5) uniform in their rules for the conduct of insured persons.

Approved societies as at present constituted do not as a whole in any sense represent insured persons, their wishes, or opinions.

Remuneration.

The remuneration of members of the medical profession working under the scheme should be determined on its merits by negotiation between the Ministry of Health on the one hand and a central body representing the profession on the other. The British Medical Association holds strongly that the remuneration of the general practitioner service should be by a capitation system, although local option might be allowed as now in the distribution of the amount allotted in each area. On the other hand, consultation and specialist work must be by tariff or sessional fees. The principle on which the amount of this remuneration must rest is that it should compare not unfavourably with that forthcoming from similar responsibility and work in private practice of a like nature, allowance being made for security on the one hand and for work done for the State or public body on the other.

The Memorandum does not reopen the question of the actual amount of the capitation fee settled by the Court of Enquiry in January, 1924, except to make two observations:—

1. That the capitation fee of 9s. is still too low to be a proper remuneration for the responsibility undertaken and work done under the insurance scheme.

2. That the extra amount allowed for rural conditions requires reconsideration.

Determination of fees for services of whatever kind must depend largely upon the nature of the insurance scheme recommended by the Royal Commission and enacted by Parliament.

Sir Leslie Wilson, Governor of Bombay, unveiled recently in that city a memorial tablet to the late Dr. J. A. Turner, who was for 18 years the zealous and distinguished health officer of the city. On Dr. Turner's death some two years ago a general movement among the citizens was organised for the foundation of a lasting tribute of respect to one who had discharged duties in connexion with the health and sanitation of Bombay with such energy and success. It was decided that Dr. Turner's memory should be perpetuated by the foundation of an annual prize in the form of a gold medal, to be named the Turner Memorial Medal and to be awarded annually to the student who secured the best position in the examination for Bachelor of Hygiene in Bombay University. The residue of any fund raised, it was resolved, should be employed in placing a medallion to Dr. Turner in the Hall for the Bombay Sanitary Institute.

MEDICAL RESEARCH COUNCIL. THE ANNUAL REPORT.

THE annual report of the Medical Research Council just issued deals, as usual, with the activities promoted or subsidised by the Council up to Sept. 30th of the previous year. The report is set out on the plan familiar to those who have come to look forward to studying in the first weeks of every calendar year an official publication which is at once a review of the progress made in this country and an index to the lines on which medical research is developing throughout the civilised world. After an introductory review of the second quinquennium in the life of the Council the report deals with the work being done in the six departments of the National Institute for Medical Research at Hampstead. The next section gives an account of progress in the determination of biological standards and in the methods of biological assay and measurement, and then experimental medicine and the research work of clinical units are surveyed. The largest section of the report, occupying 59 pages, deals with research schemes in specific subjects, and this is followed by brief reference to industrial medicine and industrial fatigue and to the interchange of travelling Fellowships between this country and America. The personnel of investigation committees for special subjects is given in an appendix, while three indices of personal names, of institutions, and of scientific subjects give easy clues to the pages on which any desired information may be obtained.

The plan on which the sections are divided is as usual partly geographical and partly according to subjects under investigation, and a certain amount of overlapping is thus inevitable. We propose to give some account of the review of the developments of the last five years given in the introduction to the report, and then to select from the mass of interesting material some examples of work in progress which appears to have a direct bearing on clinical medicine, irrespective of where it is being carried out. Much of the important work summarised in the report has appeared in full in *THE LANCET*, where there is also recorded the way in which radium and insulin, for example, from rare and expensive therapeutic agencies almost impossible to obtain have been made readily available for any individual patient. It is those aspects of the year's work throughout the country which are likely to be less familiar to our readers that we have selected for notice.

The Period 1919-1924 Reviewed.

Considering the dangers to which the cause of research was exposed by the general impoverishment following the war, the extension of facilities for medical research during this period is regarded as gratifying. Parliament has made increased provision for the universities, and thus stipends paid to those holding responsible posts are less inadequate. Private beneficence has freely supplemented Government support of research work, unfettered research professorships have been founded by bequests and gifts to the Royal Society, and the lay authorities of hospitals have become newly alive to their responsibilities for aiding the advancement of knowledge.

In the last five years considerable change has taken place in the position of the sciences contributory to medicine, and in their relation to each other and to therapeutics.

Physiology.—During the war the pressing need for bringing the best physiological knowledge to the aid of sailors, soldiers, and workers in their exposure to every kind of violence, hardship, and physical stress, brought the physiologists increasingly to their proper place within the fields of preventive and curative medicine. Moreover, it is now becoming recognised that long years of work which physicians were apt in the past to label as academic have given us the

clinical weapons of adrenalin and pituitrin and insulin. The studies of muscle function are beginning to remove empiricism from practical studies of physical training and of industrial labour, while the practical value of the new knowledge of the dietetic control of growth is now universally recognised.

The rapid rise of *biochemistry* has demanded special technical facilities which have been lavishly provided in endowed chairs and well-equipped institutes at Edinburgh, Glasgow, Oxford, Cambridge, and University College, London, among other centres. These improvements in financial provision and material equipment have been no barren ostentation. The annual output of good, original work in this subject is now more than treble that of four years ago or of any year before the war, and the progress already made is of the happiest augury for the future.

Of the present position of *pathology and bacteriology* the Council speak in less optimistic terms. They hold that the position and progress of these sciences, on which so much of the current work of medicine depends, cannot be regarded as satisfactory. It is noted that accidents of historical development have tended to divorce pathology from experimental physiology and from biochemistry, to its great disadvantage and theirs, though this separation now shows many signs of healing. They deplore the fact that the professor of pathology in some universities is still not only allowed or encouraged, but often practically compelled, to do commercial routine work, in the analysis of water and milk for public health authorities, or in the examination of material submitted by medical practitioners. At the great hospital schools the pathologist has been commonly so poorly paid that he has found it necessary, and indeed has been expected, to augment his salary by making paid routine examinations for his colleagues in practice or by taking the remunerative path of vaccine therapy. They hold that this commercial work is at best a grave handicap, and at worst a destructive influence, upon the progress of these sciences in our country, and in the national interest plead strongly for early and earnest consideration of this subject by universities and medical schools.

As to *experimental medicine and clinical research* the period under review has been of great significance, for it is just five years ago that the first "units" of medical and surgical teaching, organised on a university basis, were introduced with financial aid from public funds. The Council are of opinion that during the past five years these university clinics have wholly justified their foundation by their success, and regard them as a quite indispensable part of the national system of medical research.

Referring to the increased recognition and support recently given to *comparative pathology*, the Council point out that the science of human pathology is itself built up by experimental studies of animals, and the powers of prevention and treatment of disease, whether in animals or man, must be derived from one and the same science.

The Council suggest that the most recent gains that have come to practical medicine illustrate well this general retrospect of the positions of the contributory sciences. The work which has made a real difference to the daily tasks of preventive and curative medicine in the last few years has come from the laboratories of physiology and biochemistry rather than from those of bacteriology and pathology, and it is notable also that the chief contributions coming from the new clinics have, as it happens, been in clinical studies of the functions of the heart, the regulation of the respiratory mechanisms of the body, and the excretory efficiency of the kidney, carried out by men trained to use the precise methods of physiology or biochemistry.

Dietetics and Nutrition.

Among the most important of the broad questions being attacked by workers subsidised by the Council is that of nutrition. Problems of diet are being studied in relation to growth, gestation, lactation; quantitative and qualitative mass experiments are being carried

out on school-boys by Dr. H. Corry Mann, on cows by Prof. J. C. Drummond and Captain J. Golding, on pigs by Dr. S. S. Zilva, also in collaboration with Captain Golding, and on that convenient animal, the rat, by a large number of workers.

An interesting observation made by Prof. Drummond with Dr. Parkes is that as the deficiency of vitamin B in the diet of the male rat becomes more and more severe the ratio of the sexes of the young produced shows marked changes in the direction of an increased proportion of females. The observed differences are said to be well outside the range of possible error. Prof. V. Korenchevsky and Miss M. Carr have shown in rats that if the diet of the father is deficient in fat-soluble factor there is either no conception or, if litters are born, the offspring are eaten by the mother, probably because of their weakness. The diet of the father had, however, no influence upon the chemical composition of the skeleton of the offspring. The results of other experiments on rats tend to show that adequate maternal feeding is even more important during pregnancy than during lactation. The growth-promoting powers of particular proteins are being studied by Prof. V. H. Mottram and Dr. Gladys Hartwell.

The Special Report, No. 87, on the Nutrition of Miners and their Families, is likely to be of value both as a record of the conditions studied and as an example of the advantages and disadvantages of the method of investigation by sampling. The results of investigations into the dietaries of working-class families in various agricultural districts in Scotland will shortly be published. Dr. T. Y. Finaly has taken note of the types of feeding during the first year of life of 4000 children. It is proposed to examine the physical condition and state of nutrition of these children as they reach school age. Diet in relation to dental disease is being studied by many workers.

Cardio-vascular Diseases.

Effort has been made during the past year by Sir Thomas Lewis and his assistants, Dr. A. N. Drury and Dr. R. T. Grant, with the numerous voluntary workers from all countries attached to the Council's Department of Clinical Research and the Cardiographic Department of University College Hospital Medical School, to advance the existing knowledge of the peripheral blood circulation, with a special view to its practical application in medicine. On a full examination of the clinical phenomena of capillary pulsation, Sir Thomas Lewis has concluded that the pulsation is in large measure independent of high pulse pressure, and that it is due essentially to widening of the arterioles of the skin or mucous membrane in which it occurs. It has been shown that capillary pulsation is normal in the warmed human skin, provided that the arterioles are present and capable of sufficiently expanding, as in young and healthy persons. Further work has been done upon the condition known clinically as *urticaria factitia*, a type of rapid skin oedema following upon skin injuries. It is concluded that oedema of the skin produced by mechanical, thermal, and chemical agents is due essentially to changes in the capillary vessel walls and to their increased permeability. When the skin is injured mechanically, or by heat, the reaction is complex, but is chiefly determined by the liberation of a chemical substance locally from the tissue cells. This chemical substance, which is shown to resemble histamine closely in its action and which is held to be responsible for local phenomena (reddening and oedema) when liberated in relatively small quantities, would when liberated in larger quantities and when passing into the general circulation produce the general symptoms of shock. Since minute amounts of tissue poison are liberated in this way by injuries so mild that they are of almost daily occurrence in active people, it is suggested that the liberated substance is a chief factor in a normal mechanism of defence. Thus shock, on this view, is

provoked by an exaggeration of a normal physiological process.

Under the direction of Dr. W. E. Hume, Dr. Mona Kirkhouse has continued her work upon the therapeutic values of various diuretic drugs. The evidence gained already shows that diuretics are valuable in the treatment of cardiac oedema, but useless or harmful in cases of true renal oedema.

A cardiac clinic has been established in Glasgow under the supervision of Prof. Leonard Findlay. The cardiac efficiency of the cases is tested by the graduated exercises used by W. St. Lawrence and E. Louise Adams, of St. Luke's Hospital, New York, more recently by the use of an ergometer devised by Prof. E. P. Cathcart. Normal cases are also being tested as controls.

Tuberculosis.

Widespread efforts have been made to improve the technique of the current methods of combating tuberculosis and to ascertain whether any new ones can be commended to the attention of the practising physician. Chronic, severe cases of surgical tuberculosis are being treated by artificial light at the New End Hospital, under the supervision of Dr. Leonard Hill, who, working with Dr. L. Colebrook, has found that bactericidal efficiency of the blood is raised by exposure to certain light and heat rays. It is suggested that this enhanced power of the blood to kill microbes plays an important part in the beneficial action of sunlight upon tuberculosis and other infections. In conformity with clinical experience it has been found by experiment that irradiation for purposes of treatment must be carefully graded, since excessive exposures cause a deterioration of the blood no less striking than the improvement obtained with smaller doses.

Dr. L. S. T. Burrell has studied the treatment by artificial pneumothorax of nearly 400 cases, and will report upon these. Results of observations of the "vital capacity" in tuberculous patients show that vital capacity is of little, if any, value in forming a prognosis. With Sir Henry Gauvain, Dr. A. S. Griffith is now making experiments to determine whether tubercle bacilli in the skin or in other tuberculous tissues are killed or become modified in virulence by exposure to light rays from the Finsen-Reyn lamp. The special actions of oils and allied substances on the tubercle bacillus are being studied by Dr. Griffith and also by Dr. G. R. Ross. The important work by Sir Almoth Wright on the leucocytic reactions of the body to tuberculous infection (THE LANCET, Feb. 2nd, 1924) is summarised.

A general statement of the impressions gained in the clinical use of diaplyte vaccine, as to the value of which hopes were entertained last year, is given as follows:—

(a) Diaplyte vaccine in the dosage and by the methods used has no definite influence in checking the progress of the disease in active pulmonary tuberculosis. (b) Generally speaking, its use is contra-indicated in active febrile cases. (c) It is of some value as an adjunct to conservative treatment in tuberculosis of lymphatic glands. (d) In ambulant non-reactive cases of pulmonary tuberculosis it appears to encourage the formation of fibrous tissue. It may be a useful adjunct to sanatorium treatment. The cases treated should be those in which complete control of auto-inoculation has been secured and in which there exists evidence of beginning fibrosis.

Some clinicians, by careful adaptation of doses and their spacing to the clinical condition, have found the vaccine a useful weapon, but on the whole most of the observers have concluded that the vaccine is of no value in the treatment of tuberculosis and find its results discouraging and disappointing. It has, however, been found possible by use of diaplyte vaccine to produce an immune horse-serum having very high precipitative value against tubercle bacilli. This has allowed Prof. G. Dreyer to develop a simple precipitation method of standardising tuberculins, as supplied for veterinary or medical use, which appears to give results of an accuracy far beyond that of the indirect methods at present available (see THE LANCET, Nov. 15th, 1924).

Anticipations.

In fairness to workers, the Council cannot anticipate publication of results not yet prepared for press. In several instances, however, it has been found possible to give an indication of the promising way in which certain work is developing. Dr. E. P. Poulton and Dr. J. M. H. Campbell have worked on the clinical uses of oxygen, making extensive tests in three different types of myocardial disease varying in the respiratory symptoms present. Their results will be published in full. The report by Prof. E. Mellanby of his further studies of the rickets-producing influence of cereal foods, especially that of oatmeal, will be awaited with interest. It is hoped that by next year the family histories and hygienic conditions of about 1000 cases of rheumatism in children will have been examined by workers in London and Glasgow. In this connexion the Council express gratitude to Dr. J. Forest Smith and Dr. C. K. J. Hamilton for much voluntary help in examining children. The results of clinical trials in this country of tryparsamide, a new arsenical compound prepared at the Rockefeller Institute, may be expected at an early date. The prevalence of small-pox in this country in the year under review has provided Dr. M. H. Gordon, with the opportunity of comparing the virus of this disease with that of vaccinia, and his results will soon be available. Work in progress on the filter-passing virus of the Rous chicken sarcoma is said to be showing great promise in the hands of Dr. W. E. Gye. A report on an investigation of 100 outbreaks of food poisoning is in the press and will be issued as No. 92 of the Special Report Series of the Council. The study by Dr. John Brownlee and Prof. E. L. Collis of the occupational incidence of cancer is almost ready for publication. Inquiries into the influence of menstruation on the efficiency of the woman worker and into the psychological characteristics of the menstrual period are nearing completion.

The standardisation of insulin, which is well described in the report as a cure for diabetes in the same sense as that in which food is a cure for hunger, is in this country carried out in the department of biochemistry and pharmacology of the National Institute for Medical Research under the supervision of Dr. H. H. Dale. The department has nearly completed the important duty entrusted to it of preparing a dry stable standard of insulin, with a view to redefinition of the Toronto unit. A preliminary sample of dry non-hygroscopic insulin hydrochloride, derived from a mixture of equal contributions received from five manufacturers working in different countries, has been submitted to the Toronto Insulin Committee, in order that agreement may be reached on the exact form in which the mixed standard preparation shall be distributed. Samples will then be submitted to the experts concerned with the assay of insulin in all countries having an appropriate organisation, with a view to a comparative evaluation of existing units. When the Toronto unit has been defined in terms of the standard preparation, this should serve as a means of stabilising its value, and as a currency for its transmission to all countries. Mr. H. P. Marks has been able, while making the routine assays for potency of insulin, to devise better assaying methods. He will shortly publish a comparative method which appears to have important advantages over those hitherto in use. In this the factor of individual variation of sensitiveness is eliminated altogether, and that of day-to-day fluctuation is eliminated as far as possible.

Conclusion.

Altogether the outlook appears hopeful in many directions. We congratulate the Council on the modesty of the claims made and on the balanced, critical manner in which their report is presented. Their plans for the allocation of the grant-in-aid of £140,000 provided by Parliament for their expenditure during the present financial year are as follows: For administration expenses, £8500;

for the total expenses¹ in connexion with the National Institute for Medical Research at Hampstead, £18,500; for research grants to workers and for the expenses of researches in specific subjects at other centres in the United Kingdom, £83,000. The present personnel of the Council is as follows: Earl of Balfour (Chairman), Lord Mildmay of Flete (Treasurer), Mr. William Graham, Sir Frederick Andrewes, Prof. E. P. Cathcart, Prof. Georges Dreyer, Prof. T. R. Elliott, Sir Archibald Garrod, Dr. Henry Head, Sir Cuthbert Wallace, and Sir Walter Fletcher (Secretary). We wish them success in their constant endeavours to bring an increasing number of able men into the service of medical science.

Correspondence.

"Audi alteram partem."

ALASTRIM, PARA-SMALLPOX, AND VARIOLA.

To the Editor of THE LANCET.

SIR,—The comprehensive review by Prof. Ricardo Jorge, of which a translation was published in the last two issues of THE LANCET for 1924, is a valuable contribution to the epidemiology of an infectious disease which has given rise to considerable controversy.

Having been compelled for many years to take a special interest in the differential diagnosis of small-pox, I have read the review several times and also the article on the subject appearing in your issue of Jan. 3rd, in the hope of obtaining assistance which might enable me to distinguish alastrim or para-smallpox or amas from cases of small-pox in its discrete and mild examples. But the only features of the former conditions or condition which are brought into prominence in the review because they are the least subject to exception are the low case-mortality or the absence of fatality and the persistence of type of disease. Unfortunately, a knowledge of these epidemiological facts is of little value to the practitioner as bedside equipment. The practitioner requires clinical or other diagnostic differences. He must have much more definite distinctions for his guidance if he is to avoid calamity when small-pox is in question. Even if he is so bold as to wait and see if his patient dies or if the type of the disease persists in the succeeding generation of cases, he has not solved his difficulty, because all small-pox is not fatal and all alastrim is not equally benign, and as the "dualist" tells us, epidemics of real small-pox do occur in which a large proportion of the cases is of a mild type. In a recent outbreak in the north of London the first case which came under observation was, I believe, so benign as to give rise to considerable difficulty in diagnosis. The patient was an unvaccinated child. But in the next generation of cases there were examples of obvious small-pox of virulent type. Many similar instances of this dangerous deception on the part of small-pox might be given. How is the practitioner or the medical officer of health or the consultant to deal with a case of this type? How is he to determine whether he is dealing with small-pox or alastrim or para-smallpox? Is he to base his diagnosis on the fact that he has heard that several mild cases stated to be cases of alastrim have occurred in a neighbouring township?

In the leading article in your issue of Jan. 3rd it is stated that: "The epidemic disease . . . has qualities which, both for practical and scientific purposes, require to be differentiated from the variola or small-pox which is ordinarily understood and described in the textbooks." I cannot see how this differentiation is to be made for practical purposes in the present state of our knowledge because the conditions are clinically indistinguishable. If, for scientific purposes, we are to rely on the epidemiological argument, how many generations of benign cases will justify the announcement that we are dealing with alastrim and not with mild

small-pox? and on whom is the duty of making this announcement to be laid?

These questions are important, because in the last paragraph of the leading article already mentioned the necessity is advocated of adopting a "special term" for "the benign type of small-pox" for the sake of "clarity of thought as well as for administrative convenience." It is difficult to understand how the adoption of a special name for a sub-variety of small-pox, or for a disease which is apparently clinically indistinguishable from small-pox, will promote clear thinking, or how the special name will render administrative procedure in dealing with dangerous infectious disease more convenient. Administrative measures are brought into play by the expressed opinion of the practitioner, an opinion based on the observation of the clinical features which distinguish one disease from another. If the practitioner considers that his case is one of chicken-pox or if he notifies it as small-pox, appropriate and definite administrative procedure follows. Under existing regulations the administrative procedure which follows the notification of alastrim or para-smallpox or amas is the same as for small-pox. But if the practitioner notifies his case under any of these names, the administrative authority is hampered by the want of definite knowledge of the practitioner's opinion, a condition which promotes neither efficiency nor convenience in administration. Notification of a case under any such terms can hardly have any other effect until clinical or bacteriological or other diagnostic differences between alastrim or para-smallpox and small-pox are definitely formulated and proved.

The onus of proof rests with those who have expressed the opinion that we are dealing with a disease which is not simply mild small-pox. Until that proof is produced, discussions on nomenclature are premature, academic, and unpractical. They serve only to confuse administrative procedure in its dealings with a disease which has great potential power for social and commercial injury, and they tend to mislead the intelligent but inexperienced citizen by inducing him to believe that we have attained to a greater knowledge than we really possess. Let us wait for the proof.

I am, Sir, yours faithfully,

A. F. CAMERON,

Medical Superintendent, River Hospitals and Ambulance Service for Small-pox and Fever,
Jan. 3rd, 1925, Metropolitan Asylums Board.

To the Editor of THE LANCET.

SIR,—I have read your leading article on this subject in THE LANCET of to-day with very great interest, and am in complete accord with the views stated.

I believe the name "para-smallpox" which you suggest for the mild disease now endemic in England was first used by myself in a letter to the *British Medical Journal*, May 13th, 1922. Shortly after this I received from a medical friend, who occupies a distinguished official position abroad, a letter in which he informed me, in the language of friendly banter, that, "for foisting upon hapless humanity a terminological and etymological barbarity such as para-smallpox, I ought to be court-martialled and shot." It was with some amusement, therefore, that I learned from THE LANCET of to-day's date that the Editor had earned a similar fate.

In the last three years—and especially in the last 15 months, during which the disease has been epidemic in this borough—I have had exceptional opportunities of studying it, and the more closely it is studied, the more difficult does it become to reconcile the mild disease with classical small-pox. Clinically and epidemiologically the mild infection is a disease sui generis.

Every person interested in this problem should read carefully the excellent paper by Prof. Ricardo Jorge, a translation of which appears in THE LANCET of

Dec. 20th and 27th, 1924. The terms "alastrim" and "amaas" have no obvious meaning in English, but "para-smallpox" at once conveys to any medical mind the correct meaning—a disease closely related to small-pox. The practical advantage of this term is such that, as you suggest, its unpleasantly hybrid nature might well be ignored.

I am, Sir, yours faithfully,

R. P. GARROW,

Medical Officer of Health and School
Medical Officer, Chesterfield.

Jan. 3rd, 1925.

ACTIVE IMMUNISATION AGAINST DIPHTHERIA.

To the Editor of THE LANCET.

SIR,—You have done much during the past few years to help those interested in the public health aspects of the Schick test and active immunisation against diphtheria. They will owe you a further debt for the information given by your Vienna correspondent in your issue of Nov. 22nd, 1924, relating to the recent accident in that city, for it is only by obtaining full information such as your correspondent tried to get, that those who are using these methods can feel full confidence in their work.

The Vienna accident is the second reported within the past few years. In connexion with the first, in January of last year, Kelley (1924) reported that toxic symptoms occurred after the injection of toxin antitoxin mixture into a number of children at Concord and Bridgewater, Mass. A careful inquiry was made and it was found that some bottles of a batch of prophylactic mixture had been exposed to a very low temperature. After thawing, the contents of these bottles proved to be very toxic, whereas the toxin-antitoxin mixtures which had not been frozen were non-toxic. The effect of intense cold upon toxin-antitoxin mixtures was investigated experimentally by a number of American workers; some found that freezing increased toxicity, others did not. Mr. Glenny and Mr. Pope have investigated the problem at these laboratories and are preparing a paper for publication from which they have kindly allowed me to quote. They found that the toxicity of the mixtures they worked with did not increase after freezing. It occurred to them that the local concentration of the phenol or other antiseptic present, which takes place during freezing and thawing, would vary with the composition of the mixture and the exact physical conditions during the freezing and thawing, and that certain concentrations of phenol might be more destructive to the antitoxin present than to the toxin. They therefore tried the effect of various concentrations of phenol first upon antitoxin and toxin separately and finally on mixtures of toxin and antitoxin. They found that, if they made the phenol concentration 5 per cent. in a solution of antitoxin containing three units per c.cm., the antitoxin quickly disappeared. A similar concentration of phenol was added to a solution of toxin containing 3 L+ doses per c.cm.; about 10 per cent. of the original toxicity remained. And finally they found that non-toxic mixtures became toxic, without freezing, if 5 per cent. of phenol were added. Trikresol acted in the same manner. We have thus available a simple explanation of the increase in toxicity observed at Concord. During the freezing and thawing a local concentration of phenol occurs and the interesting dissociation and destruction of antitoxin takes place.

The only report of the second accident in Vienna available at the time of writing is that given in your issue of Nov. 22nd. Your Vienna correspondent writes: "It is well known that the antitoxin is liable to disintegrate much more quickly than the toxin." You, Sir, evidently held the same view when you wrote: "It is not safe to risk toxin and antitoxin becoming dissociated in the mixture by long keeping." I feel that this explanation is difficult to reconcile with the general experience of workers in America and

England. The Bacteriological Committee of the Medical Research Council, in referring to toxin-antitoxin mixtures, say: "No increase in toxicity has ever been observed on keeping." This view is apparently in accordance with American experience, for the official recommendation of the Bureau of Hygiene is that slightly toxic mixtures should be held until the toxicity is so reduced that the mixture complies with the official standard.

Our own experience agrees with this. Mr. Glenny has in preparation a paper giving the details of tests of the toxicity of mixtures from three months to four and a half years old. Samples were kept at room temperature, in the cold room, and in the incubator, but in no instance has there been an increase of toxicity. I may remark here that the mixtures we have worked with in these laboratories have always been adjusted to have a toxicity lower than that prescribed in the official U.S.A. regulations. Whereas 5 c.cm. of the mixtures officially allowed in America may kill acutely two out of five guinea-pigs, and may kill the remaining three with paralysis in 15 to 35 days, we have from the outset made a practice of using mixtures of which 5 c.cm. would not kill any of the animals injected within 15 days; few of the guinea-pigs receiving 5 c.cm. of the various batches of toxin-antitoxin mixture died within 21 days, and many lived and developed no paralysis. The more we know of these accidents the more certain we can be that similar accidents will not occur in future. It is obvious that no safeguards can overcome the danger if the toxicity of all mixtures is not adequately tested before their issue. Now that the danger from freezing is known, we are justified in concluding that an accident similar to that at Concord will not again occur. With regard to the second, we must await further information, but there is no evidence that the explanation put forward as the cause of the Vienna misfortune is applicable to the mixtures in use in England.

It is possible that the process of active immunisation may be considerably improved by the use of formalinised toxin, which is practically non-toxic. This interesting method of modifying toxin was apparently first described by Salkowski (1898) and investigated and used by Loewenstein in 1904 (1914). It was in use in these laboratories in 1904 for the immunisation of horses. Glenny and Sudmersen (1921) found that guinea-pigs could readily be immunised with this toxoid, and in 1923 Glenny, Allen, and Hopkins suggested its use for human immunisation. It was, later, independently discovered and investigated by Ramon (1924). A considerable amount of work with formalinised toxin has been carried out by Park and Zingher in New York, by Ramon in France, and at these laboratories. The results so far obtained are encouraging, but one is not yet ready to advocate the immediate complete replacement of toxin-antitoxin mixtures by toxoid. We can advance safely only if we proceed slowly.

May I comment on the expression "Schick serum must be fresh"? It would seem that the use of the expression "serum" when applied to mixtures of toxin with antitoxic serum is not in accordance with ordinary pathological practice, and although we owe the valuable test to Prof. Schick, whose name it bears, he had but little to do with the introduction of toxin-antitoxin mixtures, and his name is not usually attached thereto.

REX v. BATEMAN.

To the Editor of THE LANCET.

SIR,—As pathologists we were interested in the case of Dr. Bateman (THE LANCET, Jan. 3rd, p. 38), and followed the evidence of the medical witnesses closely in an endeavour to understand the facts and their interpretation by these gentlemen. From the evidence of the pathologist it appears clear and undisputed that a severe injury to the generative organs had taken place before or during the manipulations required for the delivery of the child and placenta. The most important point then to be decided was, to what extent did Dr. Bateman's after-treatment contribute to the recovery or death of the patient? In our opinion this was entirely a matter to be decided by clinicians specialising in the practice of obstetrics. The obstetricians attached to large hospitals have special facilities for gaining experience in such cases, and consequently their opinions should carry great weight and be duly respected. When we read the report of the two obstetricians it appeared to us that their evidence was clearly in Dr. Bateman's favour. To our utter dismay their opinions were apparently ignored and the case decided against the prisoner.

We are, Sir, yours faithfully,

ERNEST H. SHAW.

London, Jan. 2nd, 1925.

WILLIAM H. MCKINSTRY.

To the Editor of THE LANCET.

SIR,—This distressing case impresses upon one the fact that a large number of young medical men go out into practice with no practical knowledge of difficult midwifery at all. At least 50 per cent. of newly-qualified practitioners have never put on forceps themselves. They go into practice full of zeal for their job, are called out to assist a midwife in what may be a very difficult forceps case, and what happens—severe injury perhaps to mother and death of infant. Dr. Bateman, who through an error in judgment was instrumental in causing the death of his unfortunate patient, pays the penalty with imprisonment and professional ruin. When one considers the scale of fees payable for this class of work (viz., two guineas for a difficult case of forceps delivery, one guinea for a miscarriage, and subsequent attendance for ten days) it seems to me that if, as the result of an unfortunate accident, one is liable to imprisonment as well as the fee, the game isn't worth the candle, and I for one have withdrawn my name from the list of practitioners willing to undertake this work.—I am, Sir, yours faithfully,

Exeter, Jan. 6th, 1925.

CHARLES H. CARROLL.

To the Editor of THE LANCET.

SIR,—I am glad to observe that your columns are enabling more light to be thrown upon the tragic case of Rex v. Bateman. The need for this is urgent.

After reading the summing-up in full, which contrasts forcibly with briefer reports of it, one can no longer be much surprised at the verdict, for listening to it the average jurymen must surely have been impressed with two things chiefly: (1) That the patient suffered terrible injuries at the hands of the doctor; (2) that the doctor tried to conceal the condition after delivery.

But, whereas the injuries sustained by the patient were described and even dwelt upon in a manner which must have distressed the laymen on the jury, the clinical side of the case was not even explained, so that a calm consideration of the case as it first presented itself to Dr. Bateman was made impossible. Some of the injuries described, moreover, occur in text-book accounts of rupture of the uterus, and this fact was not put to the jury. So far as this side of the case is concerned, it is difficult to see how a medical man can hope for a just estimate of his work from a lay jury. The case of other professional people whose work involves matters of life and death—e.g., ships'

captains and military officers—is, I believe, quite different, the verdict depending upon the collective and considered advice of their professional associates and superiors.

With regard to the so-called concealment of the case, I well remember a meeting of a hospital medical society at which surgeon after surgeon got up and confessed to specific errors of technique, which had resulted, some of them, in the deaths of the patients. One admired these men for their courage and self-criticism, but no one supposed that these errors should have been explained to the patients' relations.

In his own interests, Dr. Bateman should have endeavoured to obtain expert opinion at the bedside, but the difficulty of getting such an opinion in such circumstances was pointed out by the judge, and is a terrible comment upon the system of midwifery existing in this country. As Dr. Bright Banister says in his letter in your issue of to-day, there is no evidence of a material improvement in the patient's condition justifying an earlier removal to the hospital, and the verdict of manslaughter appears to have been prompted on both scores rather upon natural feeling than upon the obstetrical evidence.

I am, Sir, yours faithfully,

Broadstairs, Jan. 3rd, 1925.

MARTIN O. RAVEN.

To the Editor of THE LANCET.

SIR,—In the case of Rex v. Bateman, as reported in your issue of Jan. 3rd, in Mr. Justice Shearman's charge to the jury Sir Bernard Spilsbury is reported to have said that it would want some considerable force, *whatever happens*, to pull away the womb; and again, that here was the womb out and there was nothing to support the pelvic floor, and the intestines must drop as soon as she got up, and something had got to be done to see that the bowels were kept from prolapsing, which means falling down, and to see that these wounds which had been bleeding were in some way sewn up or fastened so that there was a chance of her recovery; and that Sir Bernard Spilsbury particularly said unless something was done recovery was hopeless.

May I call your attention to the spontaneous pan-hysterectomy reported by Fallon¹ in which a five-para, aged 29, when two months pregnant began to have pain and flooding with difficulty in passing urine. She suspected a miscarriage and sent for a midwife, who pressed gently over the bladder and expelled the uterus which was hanging merely by a few shreds. These were cut and the mass removed. A doctor, sent for, arrived two days later (the case occurred in North Newfoundland), cut away a piece of omentum protruding through the vagina, and the woman was up on the seventeenth day and at work three weeks later. A coloured illustration of the expressed uterus is given.

It will be observed: (1) That no great force was necessary to express the almost separated uterus; (2) that no repair to the pelvic floor was necessary, nor ligation of any vessel; (3) that nothing was done, except rest in bed, yet the woman made a rapid and successful recovery. Could not torsion of the uterus with a side presentation have produced necrosis of its vaginal and pelvic attachments?

I am, Sir, yours faithfully,

Jan. 6th, 1925.

F.R.C.S. ED.

¹ Ann. Surg., Philadelphia, 1918, lxvii., 204.

SOFIE A. NORDHOFF-JUNG CANCER RESEARCH PRIZE.—Dr. Sofie A. Nordhoff-Jung of Washington, Columbia, U.S.A., founded, in the early part of 1923, this prize, designed to encourage researches in the aetiology, prevention, and treatment of cancer (see THE LANCET, 1923, i., 481). The prize as originally intended was a sum of 500 dollars, to be awarded annually by a commission composed of members of the University of Munich, Bavaria; but the commission, in agreement with the foundress, has now resolved to distribute the prize henceforth every two years only, and to increase this biennial award to 1000 dollars. The next award will be made in 1926.

Obituary.

PROFESSOR BERGONIE.

THE death of Prof. Bergonié at his home in Bordeaux on Jan. 2nd adds one more name to the roll of those gallant explorers in the unknown fields of science, whose courage and selfless enthusiasm in probing Nature's secrets is often so cruelly requited. Prof. Bergonié's state of health had offered no hope of recovery for some time past, the end was not unexpected, and the manner of his going was in keeping with the stoicism which had characterised his life of devotion to the science of medicine. His death is not France's loss alone, it is world-wide. Born at Casseneuil (Lot et Garonne) in 1857, he studied medicine at the Faculté of Bordeaux. At an early stage in his career he developed an interest in the application of physics to medicine, and became assistant to his teacher, Prof. Merguet, of Bordeaux, whom he afterwards succeeded in the chair of medical electricity. He specialised in the treatment, which has since borne his name, of employing electricity in muscular affections, and as early as 1895 devoted himself to the study of radio-active bodies. When the discovery of radium was first made known in 1898, through the work of Prof. and Mme. Curie, Bergonié threw himself into the study of the properties and applications of radium emanations, a study which he pursued indefatigably for the rest of his life. During the war he became director of the radiographic centre of the Eighteenth Region, from 1914 to 1918, and made several important contributions to the rapidly accumulating knowledge of his specialty. The hostilities over, he turned his attention more particularly to the treatment of cancer by radium. His work, however, brought its penalty, and in 1922 he was compelled to undergo the amputation from the shoulder of his right arm. Since that time Prof. Bergonié has been instrumental in founding the first anti-cancer centre in France, at the Hospital of St. André at Bordeaux. This centre was formally opened in December last, when Prof. Bergonié received, at the hands of Marshal Pétain, the insignia of the grand-croix of the Legion of Honour. In his will Prof. Bergonié desired that his body should be submitted for post-mortem examination to the Bordeaux University, and the autopsy was carried out on Jan. 3rd. He left his library to the University, and bequeathed the installation of his clinic to the anti-cancer centre, together with a sum of 100,000 francs for cancer research. His name will not be forgotten.

JOSEPH MANSERGH PALMER, F.R.C.S. IREL.

WE regret to record the recent death, after a brief illness, of Mr. Joseph Mansergh Palmer, a prominent surgeon of Ulster. Mr. Palmer, who was in his seventy-fourth year, was the eldest son of the late Mr. Thomas Palmer, Durrow, Queen's County, and was educated at Trinity College, Dublin, and the Ledwich School of Medicine. He took the licence of the Royal College of Surgeons in Ireland in the year 1872, and became Fellow of that institution in the year 1880. His professional life was spent in the city of Armagh, where he was for 52 years in the service of the County Armagh Infirmary. He was a magistrate for County Armagh, was appointed Deputy Lieutenant in 1906, and in the same year was High Sheriff of the county. Amongst other positions which he held were consulting physician to the Armagh District Lunatic Asylum, Visitor in Lunacy, consulting physician to The Retreat, Armagh, and surgeon to H.M. Prison for the counties of Armagh, Cavan, and Monaghan. He was at one time president of the North of Ireland Branch of the British Medical Association. He contributed several interesting cases to surgical literature, and enjoyed a high reputation as an operator. He took an active part in the affairs of the Armagh Cathedral Parish, and was well known in political and public life. Three of his

sons took part in the war—Commander E. M. Palmer, O.B.E., R.N., Major R. L. Palmer, D.S.O., M.C., and Lieut.-Commander I. M. Palmer, R.N.

The Services.

SMALL-POX RESTRICTIONS IN THE NAVY.

A NEW fleet order restating the provisions in reference to men going on leave to places in which an outbreak of small-pox has been notified schedules the following places as coming within the restrictions at the present time: Ashington U.D. (Northumberland), Ashton-under-Lyne (Lancs), Bolsover U.D. (Derbyshire), Chesterfield Borough and Rural District, Derby, Dukinfield Borough (Cheshire), Gainsborough U.D. (Lincs), Hucknall U.D. (Notts) (reimposed), Mansfield Borough (Notts), Melton Mowbray U.D. (Notts), Middlesbrough, Nuneaton Borough (Warwickshire) and Redcar.

ROYAL NAVAL MEDICAL SERVICE.

Surg.-Comdrs. A. C. W. Newport, N. H. Harris, and R. W. Stanistreet are placed on the Retd. List with the rank of Surg. Capt.

R. L. G. Proctor and H. E. M. Martin to be Surg. Lts. Surg. Lt.-Comdrs. (D.).—R. R. Adams to *Pembroke*, for R.N. Barracks, Chatham; A. T. Dally to *Pembroke*, addl., for R. N. Hospl., Chatham, and R.M. Infirmary, Chatham (on relief); W. C. Murray to *Pembroke*, addl., for R.M. Infirmary, Deal (on relief); J. F. Place to *Pembroke*, addl., for R.N. Barracks, Chatham, addl., temp. (on relief); and A. D. McHaffie to *Victory*, addl., for R.M. Infirmary, Eastney (on relief).

Surg. Lt. (D.).—J. L. Edwards to *Columbine*, for R.N. Hospl., S. Queensferry, and for Port Edgar Naval Base. Surg. Lt. D. Duncan to *Thistle*.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. F. S. Irvine to be Bt.-Col.
Lt.-Col. W. M. B. Sparkes retires on ret. pay.

TERRITORIAL ARMY.

Maj. (Prov.) A. F. Lee is confirmed in his rank.
Capt. E. Phillips, R.A.M.C., to be Divisional Adjut. 54th (East Anglian) Div., vice Maj. R. K. Mallam.

SUPPLEMENTARY RESERVE OF OFFICERS.

A. S. Burns to be Lt.

ROYAL AIR FORCE.

The following promotions were published with the list of New Year Honours on Jan. 1st:—

Squadron Leader to be Wing Commander: T. S. Rippon.

Squadron Leader to be Honorary Wing Commander: E. Huntley.

Flight Lieutenants to be Squadron Leaders: J. T. T. Forbes and J. Kyle.

Flight Lieutenants to be Honorary Squadron Leaders: W. R. Reith and J. W. H. Steil.

INDIAN MEDICAL SERVICE.

Col. C. H. Bensley to be Hon. Physician to the King (Ind. Mil. Forces), vice Col. Bhola Nauth, ret., and Col. H. Ainsworth to be Hon. Surg. to the King (Ind. Mil. Forces), vice Maj.-Gen. B. H. Deare, ret.

Col. G. N. Salmon, on ceasing to be empld., is placed on half pay.

The King has approved the resignation of his commn. by Capt. H. Watts-Taylor.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED DEC. 27TH, 1924.

Notifications.—The following cases of infectious disease were notified during the week—namely, small-pox, 65; scarlet fever, 1438; diphtheria, 846; enteric fever, 52; pneumonia, 944; puerperal fever, 30; cerebro-spinal fever, 2; acute poliomyelitis, 6; acute polio-encephalitis, 1; encephalitis lethargica, 44; dysentery, 8; ophthalmia neonatorum, 67. There were no cases of cholera, plague, or typhus fever notified during the week.

Deaths.—In the aggregate of great towns, including London, there were 5 deaths from enteric fever, none from small-pox (during the last 13 weeks no deaths have been recorded), 12 from scarlet fever, 35 from diphtheria, 71 from measles, and 83 from influenza. In London itself the deaths from diphtheria numbered 15 and from whooping-cough 22.

Medical News.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—Six Hunterian lectures on Recent Discoveries of Fossil Man will be delivered in the theatre of the College, Lincoln's Inn-fields, by Sir Arthur Keith, Conservator of the Museum, on the following days at 5 P.M.: Monday, Wednesday, and Friday, Jan. 19th, 21st, and 23rd, and Monday, Wednesday, and Friday, Jan. 26th, 28th, and 30th. The lectures will be illustrated by casts and preparations from the Museum and by lantern slides. During February the following lectures will be given at 5 P.M.: Monday, Feb. 2nd, Extravasation of Bile, by Prof. Zachary Cope; Wednesday, the 4th, The Pathology of Hydronephrosis, by Prof. H. P. Winsbury White; Friday, the 6th, Syphilitic Arthritis, by Prof. A. H. Todd; Monday, the 9th, Some Disorders of the Larynx, by Prof. V. E. Negus; Wednesday, the 11th, Osteitis Deformans, and its Relation to Osteitis Fibrosa and Osteomalacia, by Prof. R. Lawford Knaggs; Friday, the 13th, Regional Anæsthesia, by Prof. Stanford Cade; Monday, the 16th, The Ætiology, Pathology, and Treatment of Ectopic and Imperfect Descent of the Testis, by Mr. C. P. G. Wakeley; Wednesday, the 18th, and Friday, the 20th, The Anatomy and Physiology of the Thyroid Apparatus, by Dr. G. Scott Williamson; Monday, the 23rd, Wednesday, the 25th, and Friday, the 27th, The Nature of Tumour Formation, by Dr. G. W. De P. Nicholson.

BRIGHTON HOSPITAL SUNDAY.—As the result of the Hospital Sunday collections in Brighton, Hove, and Preston the sum of £1270 has just been divided among the local hospitals and the Royal Surgical Aid Society.

TUBERCULOSIS SOCIETY.—An ordinary meeting of this society will be held on Friday, Jan. 16th, at 8 P.M., at 1, Upper Montague-street, Russell-square, when Dr. Anthony Feiling will give a paper on Tuberculosis of the Central Nervous System.

WEST KENT MEDICO-CHIRURGICAL SOCIETY.—The fourth meeting of the session will be held at the Miller General Hospital, Greenwich, S.E. to-day (Friday), at 8.45 P.M. Dr. H. S. Knight, the President, will occupy the chair. Clinical cases will be shown by Dr. E. P. Cumberbatch, Dr. M. Davidson, Mr. H. Davis, Mr. C. A. Joll, Mr. D. C. Taylor, and others.

VIROL RESEARCH SCHOLARSHIP IN HÆMATOLOGY.—On the report of the examiners (Sir William Willcox, Dr. Alfred Piney, and Dr. Knyvett Gordon) the Directors of Virol, Ltd., have awarded the above scholarship to Mr. R. A. Hickling, L.R.C.P. Lond., Demonstrator of Pathology at Charing Cross Hospital. The scholarship is of the value of £200 for one year.

At the recent examination of the Chartered Society of Massage and Medical Gymnastics the three students who were prepared in the Massage School of the National Institute for the Blind successfully qualified—namely, Mr. E. Stitch, Mr. F. Bradford, and Mr. L. Wells. These three students are ex-Service men who have received considerable financial help from the fund for ex-soldiers organised by Captain Towse, V.C., chairman of the institute.

GUILD OF PUBLIC PHARMACISTS.—Under the auspices of the Guild a lecture will be given at St. Bartholomew's Hospital on Thursday, Jan. 15th, by Sir Robert Armstrong-Jones, entitled "The Influence of Suggestion in Social Life." Lord Stanmore, treasurer of the hospital, will take the chair at 8 P.M., and the pharmaceutical departments will be open to visitors from 7 P.M. Those intending to be present should notify A. H. Jenkin, the hon. secretary, 64, Wray Crescent, N. 4.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC.—A post-graduate course on Diseases of the Nervous System will be held at the hospital, Queen-square, London, W.C., from Feb. 2nd to March 27th. The general course will consist of clinical lectures and demonstrations, teaching in the out-patient department, and pathological lectures and demonstrations. Other courses are as follows: Lectures on the Anatomy and Physiology of the Nervous System (if sufficient applicants); clinical demonstrations, chiefly on Methods of Examination of the Nervous System; ten lectures and six demonstrations on Neurological Ophthalmology to a limited number of students (applications should be made early). Further information may be obtained from the secretary of the Medical School.

THE Scientific Press, Ltd., announce that the 1925 edition of Burdett's Hospitals and Charities, the Year-book of Philanthropy and the Hospital Annual, will be published during January.

ORDER OF THE HOSPITAL OF ST. JOHN OF JERUSALEM.—The following have been appointed Esquires: Dr. Lennox Wainwright, Dr. Walter Rogers, and Dr. Arthur Maitland Ware.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.—A course in Parasitology has been arranged by the school authorities at the tropical division of the school to supplement the teaching in other subjects for the Diploma of Public Health given at other recognised teaching centres. The course includes lectures and demonstrations in Entomology by Colonel A. W. Alcock from Jan. 17th to 22nd; in Helminthology by Prof. R. T. Leiper from Jan. 26th to Feb. 11th; and in Protozoology by Dr. J. G. Thomson from Feb. 24th to 26th. Further particulars may be obtained from the Secretary, at the temporary offices in the Institute of Historical Research, Malet-street, London, W.C. 1.

ROYAL INSTITUTION OF GREAT BRITAIN.—On Tuesday, Jan. 13th, at 5.15 P.M., Prof. A. Fowler begins a course of two lectures at the Institution, 21, Albemarle-street, London, W. 1, on the Analysis of Spectra; and on Thursday, Jan. 15th, at the same hour, Mr. Julian Huxley delivers the first of two lectures on the Courtship of Animals and its Biological Bearings. The Friday evening discourse on Jan. 16th, at 9 o'clock, will be delivered by Sir William Bragg on the Investigation of the Properties of Thin Films by Means of X Rays, and on Jan. 23rd by Dr. A. W. Crossley on Science and the Cotton Industry.

THE LATE DR. J. R. LAMBERT.—John Reginald Lambert, M.B., Ch.B. Vict., died, after a brief illness, on Dec. 26th at his home in Farsley, Leeds, aged 50 years. He was the son of the late Dr. F. W. Lambert, upon whose death he succeeded to the practice. He studied at the Yorkshire College, Leeds, and graduated at the Victoria University, Manchester, in 1897. In the same year he obtained the L.R.C.P., L.R.C.S. Edin., and L.R.F.P.S. Glasg. Dr. Lambert was M.O.H. for Farsley, public vaccinator, Poor-law doctor, and one of the medical officers at the Calverley Joint Hospital. In addition he had one of the largest panel practices in the district. He leaves a widow and a family of four sons and four daughters.

CENTRAL ASSOCIATION FOR MENTAL WELFARE.—The Association is organising with the full approval of the Board of Education a three months' training course in which the needs of teachers of classes for dull and backward children and of special difficulty classes will be specially catered for. Besides lectures on psychology and the medical aspects of the problem, every opportunity will be given to them of observing the necessary adaptation of ordinary methods of individual teaching to the special needs of the subnormal child. Throughout the course, teachers will be given opportunities of themselves teaching groups of difficult children, of learning various forms of manual work, and of taking part in classes for eurhythmics and other physical exercises. This course, however, is not a substitute for the ordinary short courses organised by the Central Association for Mental Welfare for the Board of Education, two of which are being held this year. A preliminary prospectus of the course, giving particulars of the special arrangements sanctioned by the Board of Education, may be obtained from the offices of the Central Association, 24, Buckingham Palace-road, London, S.W. 1.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—A new series of lectures arranged by the Fellowship of Medicine will be started on Tuesday, Jan. 20th, when the President of the Fellowship of Medicine, Sir Arbuthnot Lane, will deliver a lecture on the Treatment of Fractures, in the West Lecture Hall of the Royal Society of Medicine, at 5.30 P.M. The London Temperance Hospital, in conjunction with the Bethlem Royal Hospital, Central London Throat, Nose, and Ear Hospital, Royal Eye Hospital, St. Peter's Hospital, and the West End Hospital for Nervous Diseases, will hold a Post-Graduate Course in General Medicine, Surgery, and the Special Departments from Jan. 12th to 24th. A four weeks' course in Urology will take place at the St. Peter's Hospital for Stone from Jan. 12th to Feb. 7th. Clinical work will be available daily, followed by a lecture given by members of the staff.—The following courses will take place in February: A fortnight's intensive course at the North-East London Post-Graduate College (Prince of Wales's General Hospital), Tottenham;

combined course in Children's Diseases at the Paddington Green Hospital, Victoria Hospital for Children, and the Children's Clinic; Dermatology at the St. John's Hospital for Diseases of the Skin; Gynaecology at the Chelsea Hospital for Women; Tropical Medicine at the London School of Hygiene and Tropical Medicine; and Venereal Disease at the London Lock Hospital (Dean-street). Copies of the syllabus of each course and also of the January *Bulletin* may be obtained from the Secretary to the Fellowship, 1, Wimpole-street, London, W. 1.

CORONERS' INQUESTS AT LIVERPOOL, MANCHESTER, AND SALFORD.—Last year 846 inquests were held in the Liverpool Coroner's Court—a somewhat smaller number than usual. Of the total nearly 40 per cent. arose from accidents of all kinds in the streets, workshops, and factories. On an average two inquests due to motor vehicles were held every week in Liverpool. There were only ten cases of death attributed to drink, a great decrease, as in 1913 drink was indicted at 131 inquests, and at an earlier period often 200 a year. Accidental suffocation of babies has been greatly reduced in recent years. There were only 15 last year, while in 1913 the number was under 50, and not many years before that no fewer than 204 cases of suffocation of babies were recorded in a twelvemonth. There were 48 cases of suicide and 32 open verdicts were returned. Only two murder verdicts were returned and not a single one of manslaughter. The Salford coroner, Mr. A. Holmes, during 1924 held 251 inquests—145 on males and 106 on females. In 111 cases death was due to natural causes, suffocation accounted for seven cases, there were eight suicides by poisoning, and in four other deaths by poison the verdict was accidental death; 26 persons died from injuries due to falls, and 25 deaths were caused by injuries in street accidents. In Manchester the number of inquests was 625, including 29 deaths from burns, 22 scalding cases, and 18 due to suffocation. Chloroform accounted for 17 fatalities.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY, Burlington House, Piccadilly, W.
THURSDAY, Jan. 15th, at 4.30 P.M. *The following Papers will be read:* Sir Charles Sherrington, P.R.S., and E. G. T. Liddell: Further Observations on Myotatic Reflexes. Prof. A. V. Hill, C. N. H. Long, and H. Lupton: Muscular Exercise, Lactic Acid, and the Supply and Utilisation of Oxygen, Parts I., II., and III. Prof. A. P. Chattock: The Physics of Incubation. The following will be communicated by the President: H. M. Carleton: Growth, Phagocytosis, and other Phenomena in Tissue Cultures of Foetal and Adult Lung. J. F. Fulton: The Influence of Tension upon the Electrical Responses of Muscle to Repetitive Stimuli. J. F. Fulton: Some Observations upon the Electrical Responses and Shape of the Isometric Twitch of Skeletal Muscle. J. F. Fulton: The Relation between the Durations of the Isometric Twitch and of the After-action of Tetanus.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Tuesday, Jan. 13th.

THERAPEUTICS AND PHARMACOLOGY: at 4.30 P.M.

Papers:

Dr. S. S. Zilva: Recent Progress in the Study of Experimental Scurvy.

Dr. G. F. Still: The Clinical Treatment of Infantile Scurvy.

PSYCHIATRY
NEUROLOGY
DISEASE IN

CHILDREN } at 8.30 P.M.

EPIDEMIOLOGY

Special Discussion on

The Mental Sequelæ of Encephalitis Lethargica.

Opening Speakers:

Dr. P. C. P. Cloake and Dr. F. C. Shrubbsall (Psychiatry).

Prof. Edwin Bramwell (Neurology).

Prof. Arthur Hall and Dr. J. C. Spence (Disease in Children).

Dr. A. S. MacNalty and Dr. Parsons (Epidemiology).

Dr. Worcester-Drought, Dr. Edward Mapother, and others will also speak.

Wednesday, Jan. 14th.

BALNEOLOGY AND CLIMATOLOGY: at 5.30 P.M.

Paper:

Dr. Vincent Coates: Clinical Types of so-called Infective Arthritis.

Thursday, Jan. 15th.

DERMATOLOGY: at 5 P.M. (Cases at 4 P.M.)

Cases:

Dr. H. W. Barber: Lichen Nitidus (two cases).

Other cases will be shown.

Friday, Jan. 16th.

MEDICINE

ELECTRO-

THERAPEUTICS

Papers:

Sir Thomas Horder: Preliminary Communication concerning Electro-tonic Reactions of Abrams with a special reference to the "Emanometer" and the technique of Boyd.

ELECTRO-THERAPEUTICS: at 8.30 P.M.

Papers:

Dr. E. P. Cumberbatch } Treatment of Gonorrhoeal Infection
Dr. C. A. Robinson } by Diathermy.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

MONDAY, Jan. 12th.—8 P.M. Pathological Meeting. Exhibition of Specimens and Skiagrams.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, 11, Chandos-street, W.

THURSDAY, Jan. 15th.—8.15 P.M. *Papers by* Lieut.-Colonel A. T. Gage, I.M.S., and Lieut.-Colonel Clayton Lane, I.M.S., on the Alkaloids of Cinchona and Malaria. Mr. Bernard Howard and others will take part in the Discussion. The Meeting will be preceded by a Demonstration at 7.45 P.M.

TUBERCULOSIS SOCIETY, 1, Upper Montague-street, Russell-square, W.C.

FRIDAY, Jan. 16th.—8 P.M., Dr. A. Feiling: Tuberculosis of the Central Nervous System.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Jan. 12th. to **SATURDAY, Jan. 17th.**—**LONDON**

TEMPERANCE HOSPITAL, Hampstead-road, N.W. Post-graduate Course in General Medicine and Surgery.

Intensive Course. Details as per Syllabus.—**ROYAL**

EYE HOSPITAL, St. George's Circus, Southwark, S.E. Lectures and Demonstrations on Diseases of the Eye.

Daily at 3 P.M. Clinical Cases, followed at 5 P.M. by a Lecture.—**WEST END HOSPITAL FOR NERVOUS**

DISEASES, 73, Welbeck-st., W. Intensive Course in the

Diagnosis and Treatment of Common Diseases of the

Nervous System. Daily at 5 P.M., Lectures, including

Clinical Demonstrations upon selected cases.—**BETHLEM**

ROYAL HOSPITAL, St. George's Fields, S.E. Tuesday and Saturday, at 11 A.M., Lecture-Demonstrations

by Dr. Porter Phillips and Dr. Thomas Beaton.—**ST. PETER'S**

HOSPITAL, Henrietta-street, Covent Garden, W.C. Clinical Work at the Hospital daily

from 2 P.M. Special Lectures as follows: Monday by

Mr. J. Alban Andrews, Tuesday by Mr. Swift Joly,

Wednesday by Mr. Clifford Morson, Thursday by Mr.

F. J. F. Barrington, Friday by Sir J. Thomson Walker,

and Saturday by Mr. H. C. Brayshaw.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, Jan. 12th.—11 A.M., Surgical Registrar: Surgical

Wards. 12 noon, Mr. Simmonds: Applied Anatomy.

2 P.M., Mr. Addison: Surgical Wards.

TUESDAY.—11 A.M., Dr. McDougal: Electrical Dept.

12 noon, Dr. Burrell: Chest Cases. 2 P.M., Mr. Sinclair:

Surgical Out-patients.

WEDNESDAY.—12.15 P.M., Dr. Burnford: Medical Pathology.

2 P.M., Dr. Owen: Medical Out-patients.

2 P.M., Dr. Dowling: Skin Dept.

THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological

Dept. 11 A.M., Sir Henry Simson: Gynaecological

Wards. 2 P.M., Dr. Scott Pinchin: Medical Out-

patients.

FRIDAY.—10 A.M., Mr. Dudley Buxton: Dental Dept.

10.30 A.M., Dr. Pritchard: Medical Wards. 2 P.M.,

Mr. Vlasto: Throat, Nose, and Ear Dept.

SATURDAY.—9.30 A.M., Dr. Burnford: Bacterial Therapy.

10 A.M., Dr. Saunders: Medical Diseases of Children.

10 A.M., Mr. Banks-Davis: Operations on Throat,

Nose, and Ear.

Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M.,

In-patients, Out-patients, Operations, Special Depart-

ments.

ST. JOHN'S HOSPITAL, 49, Leicester-square, W.C.

TUESDAY, Jan. 13th.—5 P.M., Dr. A. M. H. Gray: The

Erythemata and Urticarial Eruptions.

THURSDAY.—5 P.M., Dr. Fagan: Demonstration of Fungoid

Diseases of Hair and Skin.

ROYAL DENTAL HOSPITAL OF LONDON POST-

GRADUATE LECTURES.

FRIDAY, Jan. 16th.—5 P.M., Mr. F. Coleman: Recent

Work on the Development of the Jaws.

ST. ANDREWS INSTITUTE FOR CLINICAL RESEARCH.

TUESDAY, Jan. 13th.—4 P.M. (at the University of Glasgow).

Prof. Cathcart: Metabolism with Special Reference

to the Kidney. Discussion to be opened by Prof.

Herring and Dr. Hynd.

UNIVERSITY OF LIVERPOOL POST-GRADUATE LEC-

TURES. (At 3.30 P.M.)

MONDAY, Jan. 12th.—(At the Children's Hospital.) Dr.

Armstrong: Clinical.

TUESDAY.—(At the Southern Hospital.) Dr. Coope:

Intestinal Intoxication.

WEDNESDAY.—(At the Northern Hospital.) Mr. Monsarrat:

Septic Fingers.

THURSDAY.—(At the Stanley Hospital.) Mr. Arthur Evans:

Surgical Cases.

FRIDAY.—(At the Royal Infirmary.) Dr. Matthews:

Medical Cases.

Appointments.

- HASLAM-FOX, H. C., M.B., Ch.B. Edin., has been appointed Whole-time Medical Officer to the Ormskirk Board of Guardians.
- JONES, J. L., Certifying Surgeon under the Factory and Workshop Acts for the Hawarden District of the County of Flint.
- LEIGHTON, T. W., PARKINSON, M.B., Ch.B. Manch., Medical Officer for Withnell (Chorley).
- MILLER, CHARLES HEWITT, M.D. Camb., F.R.C.P. Lond., Consulting Physician to the London Hospital.
- MOCATTA, SYBIL G., M.D. Lond., F.R.C.S. Eng., Assistant Surgeon to the Elizabeth Garrett Anderson Hospital.
- NANKIVELL, A. T., M.D. Lond., D.P.H. Camb., Medical Officer of Health for Plymouth.
- WARREN, ELSIE, M.B., B.S. Lond., D.T.M. & H. Camb., Acting Medical Secretary to the Zenana Bible and Medical Mission.
- All Saints' Hospital, Finchley-road, N.W.: DREADON, J., F.R.C.S. Eng., Senior House Surgeon; SPENCE, C. A., M.B., Junior House Surgeon.
- Jessop Hospital for Women: JONES, A. M., M.B., Ch.B. Manch., Senior Resident Medical Officer; SMITH, PENELOPE, M.B., Ch.B. Shet.; and JAMESON, HILDA G., M.B., Ch.B. Birm., Asst. House Surgeons.
- Kensington, Fulham, and Chelsea General Hospital, Earl's Court, S.W.: DONALD, J., M.B., Ch.B., Senior Resident Medical Officer; PARK, W., M.B., Ch.B., Junior Resident Medical Officer.
- Manchester Royal Infirmary: FERGUSON, F. R., M.D., Ch.B. Manch., Resident Medical Officer; FAIRBROTHER, R. W., M.B., Ch.B., First Assistant in Clinical Laboratory; HICKSON, S. K., M.B., Ch.B. Manch., M.R.C.P. Lond., Medical Registrar; RYRIE, B. J., M.B., Ch.B. Manch., Senior Pathological Registrar; SCOTSON, F. H., F.R.C.S. Eng., First Surgical Registrar; PANTON, J. A., M.D., Ch.B. Manch., Second Surgical Registrar; PATERSON, R. S., M.B., B.Ch. Manch., D.M.R.E. Camb., Honorary Asst. Radiologist and Electro-Therapeutist.—The following reappointments have been confirmed: DR. A. GRAHAM BRYCE, Asst. Resident Surgical Officer; DR. JOHN COWAN, Medical Officer in Charge of the Physio-Therapeutic Department; Mrs. KATE KING MAY-ATKINSON, Asst. Medical Officer in charge of the Physio-Therapeutic Dept.; DR. G. E. LOVEDAY, Director of the Clinical Laboratory; Mr. S. R. WILSON, Mr. EDWARD MOIR, Dr. T. COOGAN, Dr. G. M. BENTON, Dr. K. B. PINSON, Dr. W. SANKEY, Dr. E. FALKNER HILL, and Mrs. MARGARETTA MCLEAN POSTON, Administrators of Anæsthetics; Dr. J. HOLKER, Dr. J. D. BYRD, and Dr. J. KNOWLES LUND, Asst. Medical Officers; Mr. JOHN GOW, Mr. A. H. SOUTHAM, Mr. R. L. NEWELL, Mr. E. E. HUGHES, Mr. G. B. WARBURTON, and Dr. F. G. WRIGLEY, Asst. Surgical Officers; Mr. E. W. TWINING, Junior Asst. Radiological Officer.
- Royal Infirmary, Edinburgh: MERCER, W., M.B., Ch.B. Edin., F.R.C.S. Edin., COCHRANE, W. A., M.B., Ch.B. Edin., F.R.C.S. Edin., Assistant Surgeons.
- Salford Royal Hospital: STENHOUSE, G. B., M.B., Ch.B. Manch., Resident Medical Officer; MCCLELAND, T. A., M.B., Ch.B., B.A.O. Belf., House Physician.

Vacancies.

For further information refer to the advertisement columns.

- Birmingham, Queen's Hospital.—Med. Reg. £100.
- Bradford City Municipal General Hospital, St. Luke's.—H.P.'s and H.S.'s. Each at rate of £200.
- Brighton, Royal Sussex County Hospital.—H.S. £150.
- Cape Town University.—Asst. to Professor of Bacteriology. £500.
- Chichester, Royal West Sussex Hospital.—H.S. at rate of £185.
- City of London Hospital for Diseases of the Heart and Lungs, Victoria Park, E.—H.P. at rate of £125.
- City of London Mental Hospital, near Dartford, Kent.—Second Asst. M.O. £350.
- Derbyshire Education Committee, Derby.—Asst. Sch. M.O. £600.
- Evelina Hospital for Children, Southwark, S.E.—H.P. £120.
- Freemasons Hospital and Nursing Home, 237, Fulham-road, Chelsea, S.W.—Election of the Medical and Surgical Staff.
- Hampstead General, &c., Hospital, Haverstock-hill, N.W.—Electro-Therapeutist. £50.
- Haywards Heath Hospital.—Hon. Consulting Throat and Ear S. Hospital for Consumption and Diseases of the Chest, Brompton, S.W.—H.P. Six months. £50.
- Hospital for Sick Children, Great Ormond-street, W.C.—Cas. O. £400.
- Leeds, West Riding Mental Hospital, Menston.—Fourth Asst. M.O. £400.
- Liverpool Royal Infirmary.—Hon. Asst. S.
- Lord Mayor Treloar Cripples' Hospital and College, Alton, Hants.—Second Asst. Res. M.O. £250.
- Manchester, Ministry of Pensions Hospital, Grangethorpe.—Radiologist. £300.
- Manchester, St. Mary's Hospitals.—H.S. at rate of £50.
- Metropolitan Asylums Board.—Director Pathological Services. £1100. Also Director Diphtheria Antitoxin Establishment. £900.
- Metropolitan Ear, Nose, and Throat Hospital, 2, Fitzroy-square, W.—H.S. £150.

- National Hospital for the Paralyzed and Epileptic, Queen-square, W.C.—Hon. Anæsthetist.
- Northampton General Hospital.—Third H.S. at rate of £150.
- Nottingham General Hospital.—H.P. and H.S. Each at rate of £150. Also Res. Cas. O. at rate of £200.
- Plaistow Fever Hospital.—Second Asst. M.O. at rate of £200.
- Royal College of Surgeons of England.—Election to Court of Examiners.
- Royal Free Hospital Gray's Inn-road, W.C.—H.P.
- St. Leonards-on-Sea, Buchanan Hospital.—H.S. £100.
- St. Mary's Hospital for Women and Children, Plaistow, E.—Hon. Asst. P.
- Southwark Hospital, East Dulwich Grove, S.E.—Asst. M.O. £300.
- Sydney University, New South Wales.—Professorship of Obstetrics. £1100.
- Walsall County Borough.—Asst. M.O.H. £650.
- West London Hospital, Hammersmith-road, W.—Hon. Med. Registrar. £100. Also Hon. Obstet. Itg.
- Westminster Hospital.—S. to Ear, Nose, and Throat Dept. Also Asst. S.
- Wolverhampton and Staffordshire Hospital.—Res. Surg. O. £250. Also H.S. at rate of £150.
- The Chief Inspector of Factories, Home Office, London, S.W., announces the following vacant appointments: St. Just, Cornwall; and Staplehurst, Kent.

Births, Marriages, and Deaths.

BIRTHS.

- LANSDOWN.—On Dec. 26th, 1924, at Woodcote Grove-road, Coulsdon, Surrey, the wife of R. P. B. Lansdown, M.B., B.Ch., of a son.
- LUMB.—On Jan. 1st, at Crewkerne, the wife of Norman P. L. Lumb, O.B.E., M.B., B.S. Lond., F.R.C.S. Eng., of a son.
- LUNN.—On Dec. 28th, 1924, at Southampton, the wife of Major W. E. C. Lunn, M.C., R.A.M.C., of a son.
- ROMANIS.—On Jan. 2nd, at Harley-street, W., the wife of W. H. C. Romanis, M.C. Camb., F.R.C.S., of a son.
- WOODS.—On Dec. 28th, 1924, at St. Andrew's-street, Cambridge, the wife of R. S. Woods, M.D., F.R.C.S., of a daughter.

MARRIAGES.

- FRAMPTON—BROWN.—On Dec. 10th, 1924, at Agra, Henry James Frampton, M.C., I.C.S., to Hilda Mary Brown, M.B., W.M.S.
- JONES—WILLIAMS.—On Jan. 1st, at Christ Church, New Southgate, London, Tudor Jenkyn Jones, M.B., Ch.B., to Gladys Mary Thurlow Williams, M.R.C.S., L.R.C.P.
- RUTHERFORD—FORBES.—On Jan. 1st, at Princes-row, London, Colonel John V. W. Rutherford, T.D., M.B., C.M. Edin., M.R.C.S. Eng., J.P., to Isabella Robertson Forbes, younger daughter of Mr. and Mrs. Charles Forbes, Rohallion, Murthly, Perthshire.
- SCHLESINGER—REGENSBURG.—On Jan. 1st, at the West Hampstead Synagogue, Bernard Edward Schlesinger, M.B., B.Ch., to Winifred Henrietta, elder daughter of the late Mr. Hermann L. Regensburg and Mrs. Regensburg, of Parsifal-road, London.
- TEMPLETON—MURRAY.—On Jan. 3rd, in London, William Lees Templeton, M.D., to Christina Scott Murray, youngest daughter of Mrs. Scott Murray, of Glasgow.

DEATHS.

- CRABTREE.—On Jan. 1st, suddenly, at Ludlow, Angelo Matteo Crabtree, F.R.C.S., of Surrey Cottage, Weybridge, Surrey.
- FAGAN.—On Jan. 5th, Dr. J. Patrick Fagan, of Scarsdale-villas, W., late P.M.O., Northern Nigeria, aged 57.
- HOLROYDE.—On Jan. 3rd, at Orrest Foot, Windermere, Douglas Holroyde, M.A., M.B., B.Ch. Camb., late of Barnsley, aged 48.
- NUNDY.—On Dec. 28th, 1924, Edward Nundy, L.R.C.S., L.S.A., Barrister-at-Law, dearly beloved husband of Lily Nundy, aged 74.
- SWAN.—On Dec. 26th, at 75, Wimpole-street, after a painful illness most patiently borne, Una Gladys, the beloved wife of R. H. Jocelyn Swan, M.S. Lond., F.R.C.S.
- N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

A METHOD OF TREATMENT OF VISCEROPTOSIS.

BY CORTLANDT MACMAHON, M.A. OXF.,

INSTRUCTOR FOR SPEECH DEFECTS AND BREATHING EXERCISES
AT ST. BARTHOLOMEW'S HOSPITAL.

AN experience of the physical treatment of visceroptosis over a period of some years has established definite conclusions which I believe to be of some importance. There are very varying opinions as to the seriousness of this condition. Some hold that visceroptosis is really unimportant and is merely an incident in a condition of neurasthenia, that nearly everyone has it to some degree and that very little disability results.

That there are cases that do matter is, in my opinion, certainly true. The cases sent to me for treatment are often in a pitiable condition. One of the worst features is the condition of the mind; the memory is seriously affected and powers of concentration are markedly impaired. Physically there are weariness, flatulence, abdominal pains, headaches, and severe constipation and, in some cases, nausea. That some patients are neurasthenic there is no doubt, but I believe that the neurasthenic condition is set up by the ptosis and is not the cause of it. Some of the sufferers from visceroptosis are comparatively young women who are intensely keen to be able to resume a normal existence. Some have been troubled with abdominal discomfort from childhood, others have developed ptosis following childbirth. The child with a greatly distended abdomen and flat and contracted upper chest is surely a potential sufferer from visceroptosis unless the condition is taken in hand.

Principles Underlying Treatment.

In every case of visceroptosis it will, I believe, be seen that in addition to the abdominal muscles having given way in a more or less marked degree, the lower ribs have dropped in to a degree corresponding more or less with the advance of the abdominal wall. It is interesting to watch the act of inspiration in the visceroptosis patient. A dangerous advance of the abdominal wall is almost certain to be seen. The collapse of the lower ribs means that the large abdominal viscera no longer have their original accommodation, nor can they possibly regain it until the accommodation is given by broadening out the lower costal region so that there is ample room for them. This forms the first part of the physical treatment, the lower ribs are trained to expand eventually to a line almost or quite vertical with the axilla. Then the abdominal muscles are made to contract and pressure is applied with the hand of the operator on the lower portion of the abdomen. By advancing the pressure upwards the viscera are made to ascend, and as the accommodation provided, as explained, increases their ascent is not difficult. The patient by degrees gets an enhanced power of contraction of the abdominal muscles and eventually can often contract the abdominal wall practically to the spinal column. Each treatment with an operator lasts for 40 minutes with plenty of rest between the various series of exercises. As the lower ribs become well expanded and the abdominal muscles extremely strong, the viscera progress upwards towards their normal position with no need of help by manual pressure. Once a good position of the viscera is established no operator is required and the exercises are reduced to about ten minutes daily.

The Exercises Described.

The following exercises are those which I have found most efficacious in patients with visceroptosis. Each exercise should be carried out 18 times, with a rest after each six movements of the exercise. All the exercises should be carried out in a recumbent position, with the head and shoulders slightly raised. It is most important that the act of inspiration and expiration should be silent.

1. The operator places his hands on the side of the lower ribs level with the bottom of the breast-bone. The patient should breathe in through the nose, and the lower ribs should be felt to be expanding strongly. There should be as little movement as possible of the upper chest. When the fullest inferior lateral costal expansion is acquired, the patient should breathe out through the open mouth, and the ribs should be felt to regain their normal position.
2. The patient should breathe in in three distinct movements, and the lower ribs should be felt to expand with each breath. By degrees the expansions are increased to five movements.
3. The abdominal wall should be contracted inwards, and then allowed to recover its normal position so that an in-and-out movement is made. The operator helps this contraction by pressure on the lower portion of the abdomen. (This is a physical and not a breathing exercise. It should be carried out in series of ten contractions until 50 contractions in all have been made.)

4. The same movement as in No. 3 exercise, but the contractions are made in 1-2-3 movements instead of one movement. On each contraction the operator presses upwards with his hand, increasing the amount of pressure on each contraction.

5. Combine Exercises 1 and 3—i.e., the patient breathes in through the nose, and the lower ribs are felt to be strongly expanding. The mouth is then opened and the abdominal muscles slowly and strongly contracted so that the air is driven from the lungs.

6. The same inspiratory movement, but the breath should be held and the abdominal muscles contracted in three to five deliberate movements before breathing out. The operator helps the contraction as before.

7. The patient should breathe in deeply, the breath should be held and two more breaths taken in through the nose and, as air is inspired, two simultaneous contractions of the abdominal muscles should be made. (N.B.—This exercise is somewhat severe and at first should only be carried out six times.)

The following exercises are given so that the muscles of the chest are made very elastic, and resistance to the contracting power of the abdominal muscles is thereby reduced very considerably. These exercises are carried out with the breath held.

8. Grasp the right wrist of the patient with the left hand, carry the arm forwards, and bring it to a right angle with the body. The operator should then place his right hand well under the scapula of the patient and pull the arm backwards and downwards as the patient strongly contracts the abdominal wall. Changing the hands, do the same movement on the other arm of the patient.

9. Grasp the wrists of the patient as the arms lie at the side of the body, the operator standing behind the patient. Draw the arms outwards and upwards to above the head, pull on the arms steadily when the arms are at their fullest extent, then relax the pull. The patient should then breathe out quickly.

10. Arms as before. Bring them together in front and carry upwards to a right angle. Part the arms strongly backwards and horizontally.

11. The same exercise as the preceding one, but the arms are carried backwards at an angle of 45° upwards.

12. Commence with the patient's arms above the head, with the palms of the hands facing each other. The operator grasps the arms between the wrists and the elbows and presses the arms strongly downwards, and when the elbows approach the sides the abdominal muscles should contract. Force the elbows into the side and make the patient breathe out strongly.

The average number of treatments is six to ten. A patient who has had visceroptosis is well-advised in carrying out a modified amount of exercises daily, if only for a few minutes, so that any danger of relapse may be avoided.

Psychotherapy.—Posture.—Belts.

It is desirable to convince patients that by carrying out exercises themselves they are greatly helping recovery by their own efforts and determination. Also that, however ill they may feel, they are not suffering from any organic disease and that the chances of recovery of their health are good. It is essential to impart optimism to these patients, since they are inclined to be introspective and depressed. Exercises cannot of themselves at once obviate uncomfortable symptoms and medical treatment is generally necessary for this purpose. However, many sufferers from visceroptosis feel relief from their abdominal discomfort within a few days after commencing exercises. The stimulus given to the liver and bowel appears to cause both to function more actively and the necessity for taking strong aperient medicines is gradually done away with.

It is important that the posture and carriage of the body should be carefully observed. All movements should be strong movements. Active exercises are increased very gradually. When the patient is standing or walking, the body should lean a little forwards from the hips and the shoulders should be pressed back. This movement raises the upper chest if the rectus muscle of the abdomen, strengthened by exercises, is slightly contracted. The lower ribs, by training, are permanently well expanded and the support of the viscera is assured.

The question of supporting belts is important. Mild cases certainly should not need them, but in a case of long standing they are a necessity for a time, but, if exercises are not indulged in, they are apt to cause the muscles to become extremely weak, and the weight of the viscera is thrown into the belt with unpleasant results. By degrees the belt should be discarded at intervals, and eventually in many cases it should be discarded altogether. In no case should it entirely replace physical exercises.

Unless a patient is very weak and incapable of much effort one visit a week is quite sufficient and the exercises are carried out daily at home.

It is reported in the French newspapers that the Department of Charente-Inferieure is thinking of changing its name to Charente-Maritime, to avoid the danger of English and Americans thinking that the cognac brandy produced in the Department is "Inferior Charente Brandy." It is true that we do not often use the word inferior as meaning lower in the spatial sense. But we do know that Bad Nauheim is not bad.

THE HEALTH OF PALESTINE: A COMPREHENSIVE REPORT.

THE official census of the population of Palestine in October, 1922, was the first recorded in modern history, and the estimated population for 1923 has been calculated from the actual figures of births and deaths notified, and from the records of immigration and emigration kept by the Department of Immigration and Travel. The total inhabitants are estimated at 662,013, of whom 250,258 dwell in the towns and 411,755 in the districts (excluding Beersheba). "It is probable, on account of the greater liability of births to escape notification than deaths, that the increase of population obtained in this way has been under-estimated, which would result in an artificial increase of the calculated rates per 1000." On the other hand, deaths of infants (especially in the first month of life) in rural districts may escape notification; while in the towns, where district health offices are situated, notification of all deaths is ensured by strict control of the cemeteries. The total births recorded numbered 31,402, as against 27,516 in 1922, giving a ratio of 47.43 per 1000, compared with 42.39 in the former year; this increase is attributed to "the more settled conditions of life which prevail in the country, and to the improving social conditions of the populace." In some cases there has been an apparent decrease. In Jaffa district this was due to an error in the 1922 rate, which had been calculated on a population under-estimated to the extent of 5000. In Bethlehem, Nazareth, and Safad districts the notifications appear to have been less satisfactory than in 1922. Taking the figures as they stand, the birth ratios in the towns varied from 30.18 per 1000 at Bethlehem and 31.93 at Haifa to 61.94 at Majdal, 62.00 at Beersheba, and 64.61 at Gaza; in Jerusalem the ratio was 36.48, and for towns as a whole 42.26. In the districts (excluding towns) the average was 50.57, ranging from 35.28 in Beisan and 38.80 in Jaffa to 61.10 in Gaza and 68.41 in Safad.

Vital Statistics.

The total deaths notified throughout the country numbered 16,994, as compared with 12,172 in 1922. The ratio per 1000 (for the estimated population on July 1st, 1923) was 25.67, an increase of 6.92 over that of 1922, due chiefly to measles and its sequelae. "Regrettably the published census tables [October, 1922] only state the population by age-groups, 0-5, 5-15, &c., . . . so that the only rates which at the moment can be calculated are those of the age-group 0-5" (p. 5). On pages 8 to 12, however, the infantile mortality for 1923 "under 1 year of age per 1000 births" is fully set forth seriatim for the towns and districts; the deaths numbered 5802, giving a ratio for the whole country of 184.78, as compared with 156.56 in 1922. In the city of Jerusalem itself, where infant welfare work is carried on by the Hadassah Medical Organisation as well as by the health department, the mortality was 140 per 1000 births (p. 6; on p. 8 the ratio is stated as 141.85), as compared with 150 per 1000 in 1921 and 1922. In the other towns the infantile death ratios varied from 88.44 at Ramallah (eight miles north of Jerusalem) and 105.80 at Nazareth to 355.05 at Hebron and 444.09 at Majdal. In the districts, excluding towns, the range was from 78.71 in Nazareth and 91.65 in Tiberias to 284.08 in Majdal and 319.78 in Gaza. For towns as a whole the infantile mortality was 217.99 per 1000 births; for the districts, excluding towns, 167.88; and for the whole country, 184.76.

Incidence of Infectious Disease.

With regard to the prevalence of infectious disease, the general incidence has been low, except in the case of measles. This disease appeared (towards the end of 1922) first in Jerusalem, Gaza and Hebron being infected shortly after. There was a rapid increase in February and March, the cases reported in the latter month numbering 1338. During the summer the disease abated, until in September the total cases reported fell to 32; a recrudescence then occurred in the southern half of the country, with an extension later to the northern districts, the highest incidence (2083 cases) being notified in December. The total cases numbered 6936, and the deaths 1232. On page 17 it is stated that "the morbidity-rate for the year was 17.6 per cent."; as the case-mortality, or fatality, works out at 17.76 per cent. this ratio appears to be intended, not "morbidity." Though "this [fatality] ratio is undoubtedly raised by incomplete notification of mild cases . . . there is no doubt that the disease must be regarded as more serious in its effects on the life of the community than in European countries." Ignorance and lack of proper medical attention in the villages are the chief factors leading to high mortality; the deaths are chiefly due to broncho-pneumonia or enteritis, complicating or following the disease.

The total cases of plague numbered only 15, of which four were fatal. Its reappearance in Jaffa, which was fully anticipated after the experience of the previous year, did not take place until June. Anti-rat and anti-plague measures

had been carried out energetically throughout the winter; 1436 premises were inspected and 816 reinspected; nuisance notices were served in 644 cases, where the action required by the department had not been taken and 94 prosecutions resorted to; 364 premises were rendered rat-proof. Of 823 rats examined post mortem not one was found to be infected with *B. pestis*. There was not a single case of cholera during the whole year, but the department was prepared for action in the event of its introduction from Irak, where a widespread outbreak occurred in the autumn. Small-pox was introduced from Aleppo in January at Tiberias, where seven other cases occurred; the disease was of very virulent type, and four cases were fatal. "The customary epidemic measures were employed, accompanied by wholesale revaccination of the population of the town. Fortunately in Palestine this valuable prophylactic measure is not as yet hindered either by the profession of conscientious scruples or by the ill-advised propaganda of anti-vaccinationists. Vaccination of the population has been steadily pursued since the occupation of the country. . . . Vaccination of immigrants arriving by the ports is a routine procedure. The population as a whole is now fairly well protected, a fact which is of considerable value in view of the increasing prevalence in neighbouring territories."

The cases of enteric fever notified during the year numbered 202, of which 17 were fatal; there were also 77 cases of paratyphoid, with eight deaths. Jerusalem, Jaffa, and Haifa were mainly affected. Of the 202 enteric cases 161 occurred in the six months June to November; and of the 77 paratyphoid cases 55 occurred during the same period. The same three towns, together with Tiberias, suffered most from dysentery, which was much more prevalent than in 1922; 234 cases and 16 deaths, compared with 129 cases (11 fatal) in the previous year. The report states that "the shortage of reliable drinking water is most acute just before the commencement of the winter rains, and questionable supplies are brought into use, this probably explaining the higher incidence in October." There were 35 cases of typhus, only two fatal; the majority (18), as in 1922, occurred in Jaffa town; the disease was probably a modified type similar to that described by Brill in New York. There were only eight cases of relapsing fever, only 13 of scarlet fever, and 39 of diphtheria, as compared with 25, 83, and 83 for these diseases respectively in the previous year; seven diphtheria cases were fatal, but none of the other two diseases. Of whooping-cough 268 cases and 18 deaths were notified, Hebron and the Jaffa district being most affected. Schistosomiasis was reported in 26 cases, the source of infection in every case being either the endemic focus near Jaffa or Egypt. The public are warned against the danger of bathing in freshwater pools or streams near Jaffa, and school-children in that town are periodically examined for this condition. The large cisterns in the orange gardens surrounding Jaffa are frequently inspected, and those found harbouring *Isodora contorta* are emptied and cleansed; but the river Auja and its tributaries and adjacent marshes remain as a potential danger.

Small-pox and Vaccination.—Malaria.

Over 43,000 vaccinations with anti-small-pox calf-lymph were performed during the year, and it is satisfactory to learn that the people appreciate its value, and that opposition is seldom encountered. It is hoped that before long the department will receive sanction for manufacturing its own calf-lymph. Routine inoculation "with T.A.B. vaccine," as well as anti-small-pox vaccination, is carried out at the ports with all immigrants; and Mecca pilgrims are inoculated with "anti-cholera vaccine" and are vaccinated against small-pox before departure.

"The most successful branch of public health work during the year has been the campaign against malaria. The incidence of the disease was lower throughout Palestine than in any previous year since the occupation." The health department, with the active co-operation of the municipalities, has carried on and improved its routine measures for the control of mosquitoes in the town areas, and no new infections have occurred in any of the large towns, except Haifa. Here it has not been possible to prevent mosquito breeding in the Kishon marshes, but a scheme has been prepared for effectively dealing with them during the coming year. In the rural areas, "by enlisting the help of the landowners and villages and settlements likely to benefit; and when necessary by enforcing the provisions of the anti-malarial ordinance, drainage and reclamation schemes have been completed, the carrying out of which a few years ago was thought to be impossible without Government loan funds." The result has been a permanent reduction in the incidence of malaria. "In the valley of Jezzeel, the whole way from Merchavia to Beisan, where in previous years there have been severe epidemics of malignant malaria among the newly settled colonists, the extensive works undertaken have reduced the amount of primary malaria in 1923 to a few sporadic cases. This shows that much well-watered and

fertile land, now lying waste on account of malaria, can with one or two years' well-planned work be rendered healthy and suitable for settlement. . . . The steady diminution in malaria throughout Palestine from year to year has been due chiefly to the measures which have been taken during the last five years." During 1923, in the towns, 6792 possible breeding places were discovered. The total number of such places inspected was 933,236, of which 478,735 were oiled, and 27,336 made mosquito-proof by sealing, covering, or other means. In the villages, 3019 new wells, or cisterns, or other possible breeding places were found; 148,251 places were oiled, and 3463 closed, repaired, or made mosquito-proof.

A marked increase in the number of rabid animals at large was found throughout the country; 6571 were destroyed. In June an Antirabic Institute was established in Jerusalem, and ten treatment centres throughout the country, each supplied with "vaccine" manufactured in the department's central laboratories. The total number of persons treated was 609, and the number of treatments "carried out regularly and completely" was 544. The failure rate, "cases of hydrophobia occurring after 15 days of the completion of treatment," was only 0.56 per cent. (three deaths); the total mortality (five deaths) was 0.93 per cent. The destruction of ownerless dogs was energetically pursued, and in certain districts the Department of Agriculture carried out an effective campaign against jackals.

Hospital Administration.

In regard to hospital provision, "economy has been the feature of the year." The cost of maintenance of the Government general and infectious hospitals has been reduced from £45,000 to £20,000; their number, from 11 to 8, and their bed strength from 375 to 243. All military hospitals were closed, except the Palestine General Hospital at Sarafand (the ancient Sarepta, on the coast between Tyre and Sidon). This increased the work of the Government hospitals, especially at Jerusalem, Haifa, and Nablus; and, unfortunately, out of an establishment of six matrons, there were six resignations. The total admissions numbered 4905, a marked decrease from the figures of the three years preceding, when the patients admitted had numbered 5768, 6608, and 6646 respectively. No explanation is suggested from this decrease, which would seem to be due to want of accommodation. Of the total admissions, 36 were soldiers, 1364 gendarmes, police, and railway or other Government employees, and 155 prisoners. There were also 916 "ordinary paying patients"; and 425 prisoners were treated for minor and chronic ailments in the sick detention wards in the Jerusalem and Acre prisons and the Jaffa lock-up. The work of the Government dispensaries has been curtailed, particularly in towns where treatment at voluntary institutions was available; but ophthalmic cases (which formed 25.6 per cent. of the total treated) have been dealt with as far as possible, and at Nablus the number of new cases was nearly 10,000. In Galilee, where there are no Government hospitals, and at Gaza, where the Government hospital has been closed, the voluntary hospitals have undertaken the treatment of sick gendarmes, police, and other officials unfit for removal to a Government hospital. Several new dispensaries were opened in different parts of the country by the Jewish Co-operative Labour Association, which has a membership of 6600, provides medical assistance and food for its members when they fall sick, has clinics in places where large numbers of Jewish workmen are employed, and during the year admitted about 400 of its members to its convalescent homes—a truly excellent institution.

Maternity and Infant Welfare.

For financial reasons it has not been possible to develop the Government scheme for maternity and infant welfare. The Princess Mary Maternity Centre in Jerusalem has, however, made good progress; 128 women were admitted, and there were 111 births, as compared with 60 and 55 in the previous year. The Hadassah Medical Organisation has extended its work both in Jerusalem and in other towns, and has established a course of training for nurses in health welfare work. In Jaffa two infant welfare centres, under the New Zealand Plunket Society, have been conducted by the ladies of Tel Aviv. Another measure necessitated by reasons of economy was the permanent closure of the Travelling Ophthalmic Hospital at the end of June. During the 31 months it had been open, from 1919 to 1923, a total of 81,848 out-patients were treated, and 295 admitted to hospital; the operations performed numbered 5378. After the closure of the Travelling Hospital special attention was given to the development of ophthalmic clinics in Jerusalem and 11 other towns. These are made centres for school ophthalmic work in each district. Special or operation cases are referred to Jerusalem. The Government Mental Hospital at Bethlehem was opened in September, 1922, and now contains 40 beds, the daily average of patients present being 31.

Medical Examination of School-children.

The number of schools in Palestine in 1923 was 711, of which 314 were Government schools, and 397 "non-Government" schools, which are, however, inspected by Government medical officers. The total pupils numbered 53,467, of whom 35,703 were boys and 17,764 girls. In the Government schools the boys numbered 16,046 and the girls only 3285; in the others the respective numbers were 19,657 and 14,479. In the villages the boys in Government schools numbered 10,748 and the girls only 529; the disproportion is noteworthy. "In the Government schools the prevention and treatment of trachoma made the greatest progress during the year"; 62 per cent. of the children in these schools were affected in one or other stages of the disease, and there were 459,742 attendances at the school clinics for treatment; the results are not stated. A complete medical examination was made of 10,482 children in 294 Government schools; 5.5 per cent. suffered from enlarged spleen; in 5.3 per cent. the vision was defective; 1.5 per cent. had four or more decayed teeth; 0.5 per cent. had some lung affection other than tuberculosis; 0.3 suffered from heart disease; 0.3 from tuberculosis; and 0.3 were mentally defective.

A Comprehensive Report.

Many other subjects are dealt with in this interesting and valuable report, which contributes striking testimony to the thorough and practical character of the sanitary administration, and to the zeal and energy with which the work has been carried out, no doubt under difficult circumstances, in a country and amongst a population where sanitary science is probably neither valued nor understood. The report is most comprehensive, but bears no signature.

INTOLERANCE TO A DENTURE.

To the Editor of THE LANCET.

SIR,—Your correspondents have not solved my difficulty. I am a general practitioner, 45 years of age, and have had an upper denture fitted with a gold plate alloy. I am not the least neurotic and am in good health. Would your readers help me by suggesting any treatment to retain my dental plate? I can keep the plate in whilst eating, but almost immediately, when the meal is finished, I have to take it out owing to threatened retching or vomiting. I have tried 10 per cent. novocaine as recommended in THE LANCET recently, but it has not been a success. My mouth is otherwise normal.—I am, Sir, yours faithfully,
MEDICO.
Jan. 3rd, 1925.

NEW ZEALAND PHYSIQUE.

To the Editor of THE LANCET.

SIR,—Darwin mentions a place in South America blessed with matchless facilities for apple growing; not only were the crops unrivalled, but a ship of apple-wood thrust anywhere into the ground was nearly sure to take root and thrive. The influence of the *genius loci* may indeed be of great and peculiar strength, though less in the case of animal than of vegetable life. Still, who would have expected the wet climate of Ireland to suit so thoroughly the Arab-descended thorough-bred horse, or torrid Australia to produce a heavy wool clip, or red deer imported into the New World to double the size of their antlers in a generation? Incontestable human instances of improvement are harder to find, but California has for some time had the reputation of being particularly favourable to the physical development of the northern European, and it now becomes a question, after the familiar successes in this country of the "All Black" Rugby football team, ascribed in the main to superior speed, size, and weight, whether New Zealand should not share this reputation. There are plenty of a priori reasons why it should. Industrialism, that curse to a nation's physique (at any rate as practised in this country, with no smokeless fuel in use and practically no pit-head baths), is nearly absent there. The inhabitants are largely pastoralists, living, since the interior of the country is mountainous, mostly on or near the sea-coast. The advantages of a marine climate, among which has been lately reckoned increased sunshine, from the reinforcement of direct rays on the land by those reflected from the sea, are too well known to repeat. The one adverse factor, the slightly intemperate heat of North Island, is relieved by the sea breezes; it is jocularly said that the citizen of Wellington, the capital, may be distinguished by his habit of automatically clutching at his hat at intervals, to save it from being blown away. The clemency of climate favours, as in California, open-air life; and lastly, New Zealand has a good record in puericulture. The young Antipodean athletes may be congratulated on their successes, and their country upon being the nursery of an admirable physical type. I am Sir, yours faithfully,
GENEALOGIST.

An Address

ON

ACUTE DRUNKENNESS.

ITS MEDICO-LEGAL ASPECTS, SYMPTOMS, AND TESTS.

Delivered before the Society for the Study of Intebriety on Jan. 13th, 1925.

BY SIR JAMES PURVES-STEWART, K.C.M.G.,
C.B., M.D. EDIN., F.R.C.P. LOND.,
SENIOR PHYSICIAN TO WESTMINSTER HOSPITAL.

ACCORDING to the Oxford Dictionary, a drunk man is defined as one who is "overcome with liquor." We note that this is not quite synonymous with alcoholic intoxication or poisoning by alcohol, for a person may have taken a mildly toxic dose of alcohol which may be insufficient to overcome him and make him drunk. We naturally inquire at what stage, then, of alcoholic intoxication a person is to be regarded as drunk. This is not a mere dialectic quibble but a very practical question, for, under certain conditions, a drunken person is liable to various legal penalties.

DEFINITION.

Curiously enough, according to Byrne's Law Dictionary, no statutory definition of drunkenness exists, and "a man may be held drunk for the purpose of one offence when he would not be held drunk for the purpose of another offence. The degree of intoxication which would make an engine-driver drunk if he were driving an express train would not make him drunk if he were walking along a country lane." Mr. Serjeant Stephen, in his Commentaries on the Laws of England, defines drunkenness as "that which deprives men of their reason and occasions in them an artificial madness or phrenzy while it lasts." We medical men have to be even more precise. Therefore, with all deference to the learned legal authorities already quoted, I would submit the following definition for consideration:—

"A drunk person is one who has taken alcohol in sufficient quantity to poison his central nervous system, producing in his ordinary processes of reaction to his surroundings a temporary disorder, which causes him to be a nuisance or danger to himself or others."

In the foregoing definition two classes of transient disability are referred to. One, the intoxicated person's personal incapacity, is mainly a medical question; the other (comprising the final phrase of my definition) has to do with the relations of the drunk man to his fellow-citizens and is a medico-legal affair. In the eyes of the law (and here I am strengthened by the opinion of an eminent solicitor, Mr. H. C. Haldane) a prisoner is liable to punishment not for being merely drunk, but for the combined offences of being drunk and disorderly, drunk and incapable, drunk and unfit to drive a motor-car, and so on. I am not aware that there is now any penalty for being drunk, so long as the drunkenness does not inflict harm or risk on other people. In the reign of James I. the offence of drunkenness was an offence against public morals and convenience and was punished (4 Jac. I., Chap. 5, and 21 Jac. I., Chap. 7, Sect. 3) with the forfeiture of 5s. to be paid within one week after conviction to the churchwardens for the use of the poor. These statutes, however, appear to have been repealed by the Licensing Act of 1872 (35 and 36 Vic., Chap. 94, Sect. 12), which runs as follows (the italics are not in the original):—

"Every person found drunk in any highway or other public place, whether a building or not, or on any licensed premises, shall be liable to a penalty not exceeding ten shillings, and on a second conviction within a period of twelve months shall be liable to a penalty not exceeding

twenty shillings, and on a third or subsequent occasion within such period of twelve months shall be liable to a penalty not exceeding forty shillings.

"Every person who in any highway or other public place, whether a building or not, is guilty while drunk of riotous or disorderly behaviour, or who is drunk while in charge on any highway or other public place of any carriage, horse, cattle, or steam-engine, or who is drunk when in possession of any loaded fire-arms, may be apprehended, and shall be liable to a penalty not exceeding forty shillings, or in the discretion of the Court to imprisonment with or without hard labour for any term not exceeding one month.

"Where the Court commits any person to prison for non-payment of any penalty under this section, the Court may order him to be imprisoned with hard labour."

CAUSATION.

Alcoholic intoxication occurs when the quantity of alcohol absorbed becomes enough to poison the central nervous system, according to the above definition, and to disturb its normal reactions. The total amount necessary to produce nervous symptoms varies widely in different cases. Habituation or acquired tolerance to the drug is one factor; the seasoned toper may consume large and increasing quantities daily for many years and may never show any symptoms of drunkenness, whereas a moderate drinker, or still more a habitual teetotaler, will become acutely drunk if he attempts to keep up with him for an hour. The degree of concentration of the alcohol is another factor so self-evident as to require no further discussion. The majority of cases of alcoholic intoxication nowadays are due to spirit drinking; only in a small proportion is it attributable to light wines or beer. Another factor is the relation between drinking alcohol and the taking of food. Alcohol swallowed before or between meals—i.e., unmixed with food—is more rapidly absorbed than when taken with or immediately after food. Incidentally another curious fact is that sometimes the vomiting of alcohol, or of a mixture of food and strong alcohol, instead of preventing the person from becoming drunk, may actually precipitate the symptoms of acute intoxication. This is probably due to removal, during the act of vomiting, of the protective barrier of mucus from the gastric mucous membrane, thereby rendering the residue of alcohol which remains in the stomach more readily absorbed than before. Fatigue and excitement may also be factors in predisposing to rapid alcoholic intoxication. A sudden fall in atmospheric temperature may also precipitate intoxication. Many a man from sad experience hesitates to leave his host's fireside without an escort, owing to vivid memories of previous open-air tragedies. The most rapid method of alcoholic intoxication which I know of is by means of intravascular injection. Needless to say, this is an accidental and very exceptional affair, never self-induced by the patient.

I can recall the case of a restless young man in whom I was injecting absolute alcohol into the stylo-mastoid foramen, for the purpose of inducing temporary facial palsy so as to relieve facial hemispasm. During this injection he suddenly moved his head; consequently some of the alcohol, perhaps 20 or 30 minims, was accidentally delivered into the adjacent structures, probably into the internal carotid artery, conveying it directly to the brain. Within a few seconds symptoms of acute alcoholic intoxication supervened, with mental confusion, singing, shouting, and fighting; these phenomena subsided completely after a few minutes.

SYMPTOMS AND SIGNS.

The symptoms of alcoholic intoxication are familiar to us all (of course, I only mean by the observation of other persons). May I be allowed to recall the most important of the clinical phenomena.

The early effects of alcohol, like those of similar narcotic drugs, vary from one individual to another, affecting different parts of the central nervous system with varying intensity according to each person's special vulnerability. In moderate doses, one of its early effects is to dull the critical and inhibitory centres in the cerebral cortex. Thus the cares and

worries of everyday life are less keenly felt, so that the individual becomes temporarily happier and more sociable. The Old Book tells us how "wine maketh glad the heart of man," and if this were the end-result of alcoholic celebration many people would be none the worse and possibly the better for it. You may know the story of an eminent London physician, now dead, with a huge and complicated practice, who was asked what he did if he came home at night tired out and found an unusually heavy pile of letters waiting for him. He replied: "I drink a half-bottle of champagne at dinner and then I don't care a damn about letters or anything else." Everyone who organises a charity dinner in aid of some benevolent institution knows how alcohol tends to set free the latent generous impulses of the diners. Therefore the subscription list is never sent round until near the end of the banquet, by which time the pangs of hunger are allayed, the happy guests are sipping vintage port and smoking choice cigars, and their generous instincts are no longer subject to the same degree of inhibition as during the less altruistic period of the hors d'œuvres or soup.

Somewhat larger doses of alcohol cause pathological inhibition of various other functions, producing a mild degree of mental confusion or toxic delirium. At this stage some individuals become humorous and hilarious; others become gloomy and quarrelsome. The old dictum, *in vino veritas*, reminds us of the well-established fact that under the influence of excess of alcohol the individual's temperamental and emotional reactions, no longer controlled by the higher inhibitory centres, now reveal themselves to a critical world. One man becomes garrulous and tells stories, funny or otherwise. Another becomes boastful and aggressive, or even "fighting drunk." Another becomes sentimental and lacrymose; Englishmen call this condition maudlin, Scotsmen call it "greetin' fou." In many persons the sexual passions tend to become uncontrolled. This combination of excess in *Baccho et Venere* is familiar, and unhappily accounts for a large proportion of cases where venereal diseases are acquired by persons who in their sober senses would have taken care to avoid such infections.

Besides the higher psychical functions, the lower nerve-centres for muscular coördination, reflex tonus, &c., may also become imperfectly controlled. Thus, for example, the cerebellum may bear the brunt of the poisoning. The familiar reeling gait of acute alcoholic poisoning with inability to walk accurately along a straight and narrow path is typically cerebellar in type; it is accompanied by muscular hypotonia and by a sensation of giddiness, sometimes moderate in degree, in other cases so severe that the patient lies helpless on the ground, distressingly conscious of his condition but unable to raise his head or trunk without the most violent vertigo, causing him to collapse helplessly on the floor. Cerebellar incoördination may be brought to light by a sudden change in posture. Many a guest realises that he has dined not wisely but too well only when the moment comes for him to rise and leave the festal board. Cerebellar ataxia may also appear in the upper limbs when executing fine movements; the returning roysterer's difficulty in inserting the key into the keyhole of his home is part of the stock-in-trade of the comic journals. These ataxic phenomena are unaccompanied by nystagmus, and this would indicate that the cells of the cerebellar cortex rather than the intracerebellar nuclei are mainly disabled by the poison.

Other familiar toxic phenomena are due to disorder of the ponto-bulbar nuclei, notably those for the ocular muscles beneath the floor of the iter and for the articulatory muscles in the lower part of the medulla. The pupils are usually moderately dilated but at this stage still react to light. Double vision is not uncommon. To illustrate alcoholic diplopia, Hughlings Jackson used to tell of a Scotsman who remarked to his friend at the end of a joyous alcoholic evening, "When ye gang oot o' the door, Tam, ye'll see twa cabs. Jist get intae the first yin, for the second yin's no there."

Dysarthria or indistinctness of articulation is another familiar symptom in alcoholic intoxication, well known to the man in the street. The sufferer who tries to pronounce difficult test-phrases, such as "British Constitution," "terminological inexactitude," "sixty-sixth battery of artillery," and so on, sometimes omits a syllable here and there, or slurs his consonants into one another. In other cases he is alert enough to be conscious of his own difficulty and bravely tries to conceal it, but betrays himself by the undue emphasis with which he pronounces his words, sometimes repeating a specially difficult one twice over, to make sure that he can do it.

Alcoholic vomiting sometimes appears at this stage and may tend temporarily to aggravate the nervous symptoms as already explained; in other cases vomiting is postponed until six or seven hours later, accompanied by bursting headache, as the toxic symptoms are wearing off. The smell of the breath, and of the stomach contents if the patient is vomiting, has a characteristic indescribable aroma, probably due to the admixture of alcohol with the pharyngeal and gastric secretions. The smell of alcohol is conclusive evidence that the patient has recently swallowed alcohol but of nothing more, for it may be produced by a single glass of alcoholic refreshment. Nevertheless, uncharitable observers so often place an unkind interpretation on its presence that even temperate City men, so I am told, often chew a couple of cloves after their mid-day glass of sherry as a sort of smoke-screen. Onions, various cheeses, and other aromatics may also serve the same kindly purpose.

Hiccup, myoclonic contraction of diaphragm, is a pathological bulbar reflex due to abnormal excitation of the inspiratory centre. It occurs in cases of poisoning by alcohol, but also from other blood-borne poisons as in uræmia and from various reflex causes. Alcoholic hiccup occurs at an early or only moderately advanced stage of alcohol poisoning and is commonly associated with dysarthria.

A deeper stage of alcoholic poisoning is that of alcoholic stupor, in which the individual is unconscious, with flaccid limbs and trunk, dilated and sluggish pupils, and warm, moist skin; his temperature is subnormal and his breath, as in the lighter stages of poisoning, smells of alcohol. But even here we must be cautious in our diagnosis. The presence of an alcoholic aroma in a comatose patient, although suggestive, is not conclusive evidence that the coma is of alcoholic origin. Firstly, a patient with an attack of cerebral hæmorrhage may have had alcohol given him just at the onset of his symptoms; or whilst drinking alcohol an intercurrent attack of apoplexy may have supervened; or again, he may have fallen and sustained a head injury, producing cerebral compression. Therefore, every patient who is seen in a condition of stupor or coma coexisting with an alcoholic breath, or in surroundings suggestive of alcoholic poisoning, should be carefully examined for other causes of coma. Unilateral signs such as localised paralysis of a limb, an extensor plantar reflex on one side, inequality of the pupils, and so on, would point to a unilateral intracranial lesion. Pin-point pupils suggest either pontine hæmorrhage (often associated with a high temperature), or opium poisoning (with a subnormal temperature and a cold, clammy skin). The urine should be examined to exclude diabetic and uræmic poisoning, whilst various other poisons, especially opium, veronal, and alcohol itself, can be recognised by appropriate tests of the gastric contents, the urine, and even the cerebrospinal fluid, preferably withdrawn by cistern-puncture, if the observer is skilful enough. Typical alcoholic stupor has a less profound degree of unconsciousness than in opium or veronal poisoning or than in cerebral hæmorrhage, for the alcoholic patient can usually be roused temporarily by energetic stimulation. As the alcoholic stupor passes off, it is followed by sleep, from which the patient wakes up with an acute bursting headache, dryness of the mouth (the so-called parrot's tongue), intense thirst, nausea, and sometimes vomiting, after which he begins to feel better. The

cortical symptoms, cerebral and cerebellar, together with the diplopia, the dysarthria, and other ponto-bulbar phenomena which characterised the onset of the process of intoxication, do not recur on the "morning after the night before."

Amongst the rarer paralytic phenomena following acute alcoholic poisoning must be mentioned the tragic one of acute optic atrophy. No case of this sort, so far as I am aware, has yet been recorded in England, but it has been frequently observed in the United States especially since the days of prohibition and extensive smuggling, or as the Americans call it, "boot-legging." It results from the drinking of methylated alcohol or wood-spirit. Such a patient, after recovery from his alcoholic stupor, becomes rapidly and permanently blind owing to acute retro-bulbar degeneration of the optic nerves.

TESTS FOR DRUNKENNESS.

We now come to the practical problem which has to be solved daily—namely, whether a given individual is drunk or not. The diagnosis is often so easy that it is arrived at by what trade-unionists would term unskilled labour—i.e., by non-medical observers. As a matter of fact, in most cases the diagnosis is made by a policeman, who has then to decide whether to take the person into custody, for the safety of the drunk man himself or for that of his fellow-citizens. At the police-station the police officer's diagnosis is confirmed or otherwise by the police surgeon, who may be too open to suggestion. And here I would like to make it perfectly clear that in nine cases out of ten the policeman's diagnosis is correct.

A good deal of loose thinking has been going on upon the subject of so-called tests for drunkenness. With the possible exception of a positive reaction for alcohol in the cerebro-spinal fluid, to which I shall refer later, there is no single clinical sign which is pathognomonic of alcoholic poisoning of the central nervous system, because drunkenness is not a simple clinical entity like a broken bone or a consolidated lung, but a way in which certain nervous tissues react, evidenced by a whole series of transient phenomena following an initial poisoning.

The first question we always have to ask ourselves is, "Has the person recently taken alcohol?" If he has not, we need proceed no farther. If we smell alcohol in his breath, this is *prima facie* evidence of the possibility of alcohol poisoning, but only so far as it goes. And, by the way, it is important that the observer who claims to recognise the smell of alcohol in others, whether he be a police-officer or medical officer, shall himself be free from recent alcoholic consumption. Second, has he taken alcohol in such quantity as to produce disorder of the central nervous system and to render his reactions to the outer world temporarily abnormal? This is where the various so-called tests for drunkenness come in. But it must be remembered that these are not tests for alcoholic poisoning itself, but only for cerebral, cerebellar, ponto-bulbar, or other disorders. Such disorders may be due to alcoholic intoxication, but they may also be produced by various other causes. Take, for example, the common case where a policeman arrests a man for being drunk and incapable in a public place. When asked in the witness-box what was the condition of the accused, the constable usually replies confidently and dogmatically, "He was drunk." If pressed by the court or by the defending counsel to say how he knew that the accused was drunk, he generally says, "He smelt of drink; he was disorderly in his conduct; he spoke indistinctly; and he staggered in walking." Such facts as these are certainly strong presumptive evidence of drunkenness. But, being human, even a policeman may be mistaken, for, apart from the smell of alcohol, everyone of the foregoing evidences of drunkenness may be found in certain persons who are perfectly sober. As crude examples of what I mean, it is easy to understand how an individual with the unsteady gait of locomotor ataxia or of cerebellar or labyrinthine disease, or a patient with dysarthria

from bulbar palsy, palatal deficiency, or even with a stammer, or another who is nervous, angry, or emotionally excited from perfectly legitimate cause, say after a street accident, may quite innocently be charged with being drunk. How are we to avoid such errors? Sometimes by obtaining evidence as to the presence of these disabilities before the onset of the alleged intoxication, and in any case by examining him after the supposed drunkenness has had time to pass away when, if he is suffering from a gross organic lesion, he will still be found to display the same clinical disorders, with the exception that the alcoholic aroma has now faded from his breath "like the snows of yester-year."

A little while ago a medical colleague, who suffers from a large perforation of the palate, together with chronic Eustachian catarrh and frequent labyrinthine vertigo, was driving his motor-car when he had to swerve to avoid someone at a street corner. His car ran on to the side path, bruising the legs of a bystander. As bad luck would have it, he had recently had a glass of gin and vermouth. The police-constable, noticing his alcoholic breath and observing his unsteady gait and indistinct articulation, promptly, and quite reasonably, arrested him. He was accused, and convicted, of being drunk in charge of a motor-car. Only on appeal was he able to establish the facts of his chronic palatal deficiency and recurrent labyrinthine vertigo and to secure acquittal on the charge of drunkenness.

In doubtful cases the court, in my opinion, should insist on a second examination being carried out more frequently than it does at present, which is almost never.

Common Clinical Phenomena Used as Tests.

Let us now briefly consider some of the commoner clinical phenomena employed by medical men as tests in the recognition of drunkenness at a given moment. And once more let me emphasise the fact that these are not in themselves tests for alcoholic poisoning, but merely for cerebral, cerebellar, or ponto-bulbar disorders, as the case may be.

Disorder of the higher cerebral centres may be evidenced by the presence of mental confusion, incoherence of thought and speech, emotional excitement on the one hand or apathy on the other. Sensation may also be disordered so that the patient is relatively insensitive to stimuli, especially painful stimuli, and may cut, bruise, or otherwise injure himself without noticing it. Such cerebral phenomena when transient, of recent origin, and associated with a recent dose of alcohol, are strong presumptive evidence of drunkenness. But we have to bear in mind the possibility that the patient may be habitually emotional or excitable, that he may have recently sustained some acute emotional or physical shock adequate to produce these phenomena in a perfectly sober person, or that the patient may be actually insane.

Cerebellar disorder is recognised by its characteristic incoördination of voluntary movement and by its muscular hypotonia. It is most readily detected in the lower limbs. The reeling cerebellar gait, whether from alcoholic poisoning or from other causes, is noticeable by onlookers and sometimes by the patient himself, who takes "more than his share of the pavement." Amongst the common manoeuvres for eliciting the presence of cerebellar ataxia, a favourite one is to ask the patient to walk along a straight and narrow path, then to turn quickly and come back again. The more difficult feat of walking heel-and-toe along a chalk line is an entirely artificial test which quite a number of sober persons may fail to accomplish. Failure to stand on one leg with the eyes shut, of which I have recently read as a supposed test of cerebellar disorder, is a mild acrobatic feat which the most sober of us might easily fail to execute during the emotional excitement following police arrest. The most exemplary abstainer may well feel apprehensive if he falls into the hands of a medical officer who exacts so high a standard of cerebellar efficiency.

Cerebellar ataxia of the upper limbs is conveniently tested by asking the patient to place one finger quickly on our own finger-tip, or to raise a glass of

fluid (water, of course) to his lips, or to carry out the more domestic ordeal of putting a key into its keyhole. In cerebellar disorder these movements are performed jerkily, partly owing to deficient muscular tonus and partly from inability correctly to estimate the range, so that the patient cannot arrest the movement at the desired target but either plunges past it, or may underestimate the range of movement and stops short before reaching the mark, finally swooping down on it with excessive force.

Tabetic ataxia of the lower limbs may be mistaken for drunkenness, but only by a careless medical observer. Unlike cerebellar ataxia, tabetic ataxia is aggravated by closing the eyes. Absence of the ankle-jerks and usually also of the knee-jerks, together with the condition of the pupils, &c., will usually prevent a mistaken diagnosis of this sort.

Turning now to the phenomena of *ponto-bulbar disorder*, dilatation of the pupils is a sign upon which considerable emphasis has often been laid. In my opinion, its importance is often exaggerated; the pupillary dilatation in alcoholic intoxication is usually moderate in degree, and in slighter degrees of intoxication sometimes absent. In alcoholic stupor, on the other hand, dilatation of the pupils is the rule with sluggish response to light.

A few days ago, when sitting at a table in a Pullman carriage, during a short railway journey of an hour and a half, I found myself opposite a fellow-passenger who consumed, under my own eyes, five large whiskies-and-sodas in rapid succession, thereby incidentally providing me with an opportunity of studying with ease and comfort the onset of toxic nervous phenomena. Towards the end of the journey he became mentally confused, happy, noisy, and slightly dysarthric. As he leaned hospitably across the table to offer me, although a complete stranger, the compliments of the season, I carefully observed his pupils; they were not dilated and reacted normally to light.

Transient weakness of the external ocular muscles is frequently produced during the process of alcohol poisoning. In its milder degrees it manifests itself by deficient power of convergence, and when combined with mild cerebral symptoms which so frequently coexist, this helps to account for the drunk man's difficulty in visual fixation and for his characteristic fatuous look. A somewhat greater degree of weakness of the ocular muscles produces double vision, a symptom which usually impresses itself even on the sufferer's fuddled consciousness. Disorder of lower bulbar nuclei may produce temporary indistinctness of articulation or dysarthria. We must be careful to exclude dysarthria from various organic causes, whether in the brain-stem or bulbar nerves, or in the palate, lips, or tongue. Moreover, ocular and bulbar symptoms, not unlike those of alcoholic poisoning, varying in degree and sometimes of transient duration, are also met with in *myasthenia gravis*, admittedly a rare disease.

Amongst the *vascular and visceral phenomena* indicative of disorder of the vegetative nerve-cells, some of which are situated within the brain-stem, we may mention the flushed face, rapid pulse, and warm, sweating skin, also the occurrence of salivation and vomiting, although this latter symptom may be partly gastric in origin.

The pupils, when they happen to be dilated, still preserve their reaction to light, contrasted with the extremely dilated and insensitive pupils of poisoning by belladonna, hyoscine, and similar drugs.

Disorder of the reflexes, in my opinion, is of no practical value in the recognition of alcoholic poisoning. Exaggeration of the knee-jerks and other deep reflexes is sometimes mentioned by medical officers as a sign indicating acute alcoholic poisoning, but the degree of briskness of these reflexes varies so widely in normal individuals that we cannot regard their exaggeration as of any diagnostic significance. Ankle clonus never occurs from acute alcoholic poisoning; nor do we find extensor plantar responses, which may be present in uræmic coma or that of poisoning by opium, sulphonal, veronal, or coal-gas.

UNCONSCIOUS STAGE OF ALCOHOLIC INTOXICATION.

In the deepest stage of alcoholic intoxication, when the whole brain is inactive with the exception of the vital medullary centres, there results a condition in which the patient is unconscious with flaccid limbs and trunk. The depth of unconsciousness ranges from stupor to coma, according to whether the patient can be roused from his unconsciousness or not by energetic stimuli. In profound alcoholic poisoning stupor and not coma is what we find, even when the patient is what is called "dead drunk." In recognising the cause of such unconsciousness the *smell of the breath* is of value, with certain limitations to which I have already referred. Alcoholic stupor is usually associated with a warm, moist skin, and accompanied by the characteristic alcoholic odour, coexisting with fairly wide dilatation of the pupils, which still react to a bright light. The odour of the breath may point to poisons other than alcohol. The smell of opium is characteristic when laudanum has been taken by the mouth, and in opium or morphine poisoning the pupils are closely contracted. The toxic coma of uræmia is often accompanied by a urinous odour in the breath and that of diabetic coma by the sweet hay-like smell of acetone.

Analysis of the urine is helpful in cases of deep unconsciousness. In alcoholic poisoning alcohol can be detected by adding bichromate of potassium solution followed by a few drops of strong sulphuric acid; if alcohol is present, a bright green colour appears, together with a smell of aldehyde. Another simple test is by adding an equal quantity of a strong solution of iodine in iodide of potassium, followed by a few drops of caustic potash, drop by drop, until the iodine is decolorised. Iodoform crystals are produced, accompanied by a characteristic odour. Other substances should also be looked for in the urine in cases of unconsciousness. Patients with diabetic coma will show not only sugar but also oxybutyric acid, aceto-acetic acid, and acetone. The presence of albumin, on the other hand, together with casts and epithelial elements, is suggestive of uræmic coma, although in some cases of interstitial nephritis albumin and casts may be scanty or absent.

Tests can also be carried out on the *cerebro-spinal fluid*. To my mind the presence of alcohol in the cerebro-spinal fluid is really the only sign at our disposal which can be regarded as pathognomonic. If positive, it is conclusive evidence of alcoholic poisoning which has actually reached the central nervous system. Unfortunately, it is not always feasible to carry out lumbar or, still more, cistern puncture. Through the kindness of my house physician, Dr. J. G. Wilson, I have recently had the cerebro-spinal fluid analysed for alcohol in three recent cases of severe alcoholic poisoning, with a positive result in each case. Incidentally, in uræmic coma urea is present in excess in the cerebro-spinal fluid and an excess of sugar in diabetic coma.

SUMMARY OF DIAGNOSTIC PROCEDURE.

Let me here offer a short summary of the procedure suitable to be adopted when we are called to see a comatose patient:—

First we inquire into the history, as to the patient's previous health, whether he has recently had a head injury, under what circumstances he was discovered to be unconscious, whether the unconsciousness was sudden or gradual in onset and whether it was preceded by other symptoms such as convulsions or headache. We then examine the patient, feel the head for signs of injury, smell the breath, examine the pupils, noting their size, equality or inequality, and their reaction to light. We examine the heart and note the character and frequency of the pulse and respirations. We note the radial systolic blood pressure and measure it by a manometer if possible. We observe whether the face is symmetrical or not, and whether there is conjugate deviation of the head and eyes in any direction. The optic discs and fundi should be examined in all cases of coma or stupor. We lift the limbs in turn and let them fall, observing whether

there is any difference between the flaccidity of the two sides. We test the knee- and ankle-jerks and examine the plantar and abdominal reflexes on both sides. Then we pass a catheter, draw off the urine, note its specific gravity, and test it for albumin, for sugar, and for acetone. Finally we note the temperature in both axillæ, and in all doubtful cases we perform a lumbar or cistern puncture and examine the cerebro-spinal fluid. In patients from malarious districts we should also examine a blood-film for the malaria parasite.

Looking back on the successive stages of alcoholic poisoning of the nervous system, it is evident that the average case of drunkenness presents little or no difficulty in diagnosis. The really difficult cases are at the two extremes of the series—namely, those in which the impairment of cerebral function is very slight and those in which it is so profound as to cause deep unconsciousness or stupor.

Let us take the slighter cases first. In such cases two distinct and successive facts must be proved to have occurred in order to establish a diagnosis of drunkenness. First, it must be shown that the person has recently taken alcohol. The immediate antecedent history of the case, the surroundings under which the person came under observation by the police, the alcoholic odour of the person's breath, are all suggestive, so far as they go, but not conclusive. Whilst a drunken man's breath will usually smell of alcohol, so may a perfectly sober man's, otherwise it would be dangerous for an archbishop to drink a glass of sherry with his lunch. Conversely, the absence of alcoholic odour in the breath, so far as it goes, is against the presence of alcoholic poisoning. Second, the reactions of the person's central nervous system to his surroundings must be shown to be temporarily so disordered as to be injurious to himself or others.

If a person already suffers from disease of the central nervous system, thereby presenting corresponding cerebral, cerebellar, ponto-bulbar, or other symptoms, and happens to come under observation after taking alcohol in the most moderate amount, he may easily be the victim of an injustice. But in such a patient the phenomena will not be temporary; they will be present both before and after the alleged alcoholic poisoning. Apart from pre-existing diseases of the nervous system, even anatomical abnormalities, such as deformities of the lower limbs, have been known to give rise to mistakes. I remember the case of a taxi-driver with deformed feet who had the misfortune to be arrested on a cold winter's night outside a bar after consuming a single glass of ginger wine. A police officer, quite reasonably, suspected him of being drunk, but subsequent investigation showed that the man's deformity was the adequate cause of his chronic insecurity of gait.

Excluding people with pre-existing disabilities of various sorts, and coming to temporary disorders of function, we have a class of persons in whom transient excitement—e.g., the fact of being arrested—may simulate alcoholic poisoning of the central nervous system. This is really the most difficult case of all. Where the decision is doubtful, it is the duty of the medical officer, resisting the human tendency to corroborate without careful consideration the snapshot diagnosis of the police-constable, to give the patient the benefit of the doubt. And I am sure that many medical officers do pursue this course. If an excited person, examined in the humiliating environment of a police-station, is nevertheless able to give a clear and coherent account of his recent doings, his transient excitement and indignation are not necessarily evidence of toxic cortical disorder. If his breath does not smell of alcohol, this is in favour of sobriety; on the other hand, if it does smell of alcohol, this, so far as it goes, is in favour of alcoholic poisoning. But again I would insist that even the combination of an alcoholic odour with emotional excitement is not sufficient evidence of cerebral disorder due to alcohol.

Matters are different, however, in cases where, superadded to the alcoholic breath and emotional excitement, we have, as is so commonly found, incoherence of thought and speech together with

signs of temporary cerebellar and ponto-bulbar disorder. Unsteadiness of the limbs, evidenced by a staggering gait and by difficulty in performing coördinated movements such as pointing to or picking up a small object, true dysarthria, known to be different from the sufferer's ordinary articulation, and diplopia, if it can be demonstrated, are, all of them, definite evidence of disorder of central nervous mechanisms. Accessory phenomena, inconclusive by themselves, such as hiccup, a warm, moist skin, flushing of the face, &c., are valuable corroborative signs. To my mind the best physical evidence of all is a positive reaction for alcohol in the cerebro-spinal fluid. It must be admitted, however, that few persons are likely to submit voluntarily, and fewer still are likely to volunteer, to have this valuable diagnostic procedure carried out.

In the deeper stages of alcoholic poisoning where stupor has supervened, the history and surroundings of the case, together with the appearance of the patient are usually characteristic, but we must always be careful to exclude the possibility of other varieties of coma, not only from outside poisons (such as opium, veronal, ether, the late stages of belladonna and hyoscine poisoning, and so on), but from auto-genous toxins as in diabetic and uræmic coma. Gross vascular lesions must also be borne in mind, such as cerebral or pontine hæmorrhage, and traumatic lesions, as in head injuries.

There is no short cut to accurate diagnosis. Our only safe guide is by means of careful and systematic clinical examination. The main difference between a superior medical opinion and one which is less valuable, is not that the one man necessarily knows so much more than the other, but that he is wise enough to make a more careful and more accurate examination of his cases.

The Relation

OF

MEDICINE TO THE NATURAL SCIENCES.

A Presidential Address delivered to the Science Masters' Association on Jan. 5th, 1925.

BY SIR BERKELEY MOYNIHAN, BART.,
K.C.M.G., F.R.C.S. ENG.,

PROFESSOR OF CLINICAL SURGERY, UNIVERSITY OF LEEDS.

[In the earlier sections of his address Sir Berkeley Moynihan traced from prehistoric times, through Grecian and Roman civilisation, the concept and development of the scientific idea—"the idea that the world in which we live is governed by laws, that the laws can be formulated by a close observation of their methods of working and by their failures to work, and that by experiment the processes by which they work can be tested." He then showed how the science of the Greeks from the first to the last was the child of Medicine; Hippocrates was the true originator of inductive logic, but his followers for centuries added nothing to the science or the art of medicine, being only concerned with following uncritically the teachings of the master. He alluded to the one great exception to an acquiescence in tradition which marked five centuries—namely, the famous anatomical work done at Alexandria. Later came the experimental work of Galen, the parent of the deductive method, and he with Hippocrates ruled the science of medicine until at the Renaissance, Bologna, Padua, and Salerno became centres for the study of medicine. There followed a great development of natural science largely due to medicine, which, said Sir Berkeley Moynihan, "has in truth proved the fairy godmother of many of the natural sciences," for Copernicus, whose views were later confirmed by Galileo, was a medical man, and William Gilbert, the

author of "De Magnete" and the founder in modern times of experimental science, was also a physician. Among famous chemists and physicists who have been doctors of medicine, the lecturer mentioned Robert Boyle, John Mayow, Boerhaave, W. H. Wollaston, the inventor of the reflecting goniometer, and Young, who revived and established the undulatory theory of light and unlocked by the Rosetta stone the mystery of hieroglyphics. To these may be added the Florentine physician known as Steno, the discoverer of the parotid duct, who was a pioneer in mineralogy, while the famous Linnæus was a Doctor of Medicine. Sir Berkeley Moynihan continued:—]

The influence of medicine, and of the training that a career of medicine necessarily involved, has therefore been very considerable in the creation and in the development of many of the natural sciences. Yet for several centuries the growth of medicine hardly kept pace with the slowest of its intellectual children. For despite a few but most conspicuous exceptions the methods were sterile methods; they were deliberately designed to search the ancient written words, and were timorous or disdainful of contact with the raw truths of daily experience. A search in the common law, however industrious, and however ingenious and protracted, can reveal nothing that is not therein contained. Criticism, exposition, interpretation, correlation of any text, however honoured, can never lead to discovery; no creative act is thereby involved. And medicine for generations was turned in upon itself, and sought no new experience.

It is not difficult now to see some reasons for this long delay. In organic diseases there are structural changes in the tissues. These structural changes had never yet been studied with care, because of the indignity of manual employment, nor had any of the morbid parts been submitted to examination by the microscope. The science of pathological anatomy created by Morgagni (1682-1771) and by John Hunter gave for the first time the opportunities of correlating the symptoms observed during the lifetime of a patient with the changes found on examination of the body after death. To examine these changes during the life-time of the patient was not possible, for every wound was serious, and any opening of a body cavity almost inevitably fatal. Lister's work, founded upon and inspired by the work of Pasteur, made all surgical procedures safe, and gave to surgery the strongest weapon ever forged, not only for the relief and cure of disease, but also for the pursuit of a purposeful inquiry into structural changes in the bodies of those afflicted by disease, in an early stage of the morbid changes. So at last the two methods of scientific inquiry, after so long a divorce, came together. Observation could be tested by inquiry into the pathological changes then present; and analogical research could now safely be conducted upon the bodies of animals.

THE EXPERIMENTAL METHOD IN MEDICINE.

The tendency in modern medicine is unhappily threatening to go astray. The methods of experiment, necessary though they are to all right and rapid progress, have been given an undue relative importance and have been regarded as the chief, or even the only, means by which truth can be discovered or established. In the physical sciences observation, hypothesis, and experiment are, perhaps, the whole story, and of chemistry, which seems more and more to become a province of physics, the same is true. In other sciences experiment may play no great part, our knowledge being chiefly gained by observation, and by a steady, if slow, progress from individual and isolated truths to a universal law. Of such geology is, perhaps, the best example. In medicine there should be a close confederacy between observation and experiment; but in observation there lie difficulties far greater than in any other science, and in experiment we may often argue only by an analogy. To observe with accuracy in the physical sciences is a matter which chiefly concerns the trained observer; the cold facts presented are there, without distortion and

free from gloss; power of perception and of interpretation, patience, and strict intellectual integrity on the part of the recorder are the chief qualities required. In medicine the conditions are not presented with the same simplicity. The symptoms, and even sometimes the signs, of disease are coloured by the personality of a patient, and may be hidden behind a veil that at first seems quite impenetrable. To elicit a true anamnesis demands, not seldom, the most inexhaustible patience, the most acute perception of relevancies; an accurate measurement of those deflections from truth which are the unconscious results of a patient's temperament or fleeting emotions; the re-examination of first impressions in the light of later revelations, each step being taken without prejudice. All this is more anxious and more difficult than any placid observations carried out in the laboratories, and needs a different and, I hold, a far sterner training. The close and continued observation of a multitude of facts, at first apparently disjointed and irrelevant, each captured only by surmounting difficulties that may baffle one repeatedly; the exercise of an unbiased faculty of reason upon all these until each takes its true place in the series, and the combination of observed and appraised truths into an accurate diagnosis or prognosis may require the full exercise of the powers of the mind. The Hippocratic method still finds an arduous and its noblest use in the science and in the art of medicine. When so much has been won from ignorance each step in the progress may then be tested, illustrated, or explained by experiment. We must, as Harvey said, seek out the secrets of Nature by way of experiment. But, again, it is only observation that discovers exactly where the secrets lie, what the experiment should be, and precisely what it is asked to explain. Yet experiment upon animals in the laboratory touching any knowledge gained by contact with the disease of man may be open to error. Such experiment is necessary upon a scale far larger than any upon which we in this country are permitted to engage. The lessons to be learnt are innumerable and of high value. But we must not repeat the error of Galen, and argue "analogically" with too ready an acceptance of the accuracy of the analogy. Experiments may and do reveal much of the intricate processes of physiology, but in pathology their value is a little restricted. So many factors enter into the origin, the course, and the interpretation of disease in man that nothing exactly similar can be expected to occur in animals. This warning seems necessary. For close as the relationship between laboratory methods and clinical experience should continue to be, we cannot fail to recognise that it is clinical experience which must govern our decisions, and that laboratory methods are chiefly necessary as auxiliaries and as illustrations rather than as final and controlling influences. We have not proved ourselves free from the grave error of allowing the clear and irrefutable evidences of clinical experience to be placed in a position of subservience to the disclosures of the laboratory. The proof of the validity of laboratory works in connexion with human diseases is not their success in the test-tube or retort, but in the effects witnessed when applied to the patient in clinical work. The physician or the surgeon must needs pay due regard to all the help that can be gained by the researches, the tests, the relevant experiments of the laboratories; but the right appraisal of the value of each, and the use of the knowledge so placed at his disposal are his responsibility alone. For a disease is not the sum of its symptoms, nor of its chemical or microbic reactions, but is a morbid state in a living patient; and it is in dealing with his patient, when fully cognisant of all that can be learnt of him, that the physician proves his power.

SURGERY: ITS HIGHEST FORM.

The highest form of the experimental method in medicine is that which surgery offers. As by swift changes surgery has grown safer and still more safe, until at last it can be claimed that a further increase

of safety for the patient can only depend upon an earlier access of the surgeon to him, the therapeutic side of our craft has not remained the only one. Surgery is now a strong arm of research, and has accomplished much in many directions. In the last half century the operation theatre has proved to be a most procreant laboratory. Our knowledge of all abdominal diseases has been so greatly and so quickly changed by operative research, that a complete revolution in thought and in action has resulted. I can think of few researches which compare either in scientific or in therapeutic importance with those which have been made by the surgeon during the last 50 years. Certainly no more fruitful combination of the inductive method with the method of apposite and felicitous experiment has ever been known. We look forward now to a time of help from our laboratory associates which may bring us to an understanding of the causes of those local diseases whose consequences alone are eradicated or rendered less injurious by the operations we perform. The first step at least has already been won by the surgeon in demonstrating the inter-relation of various morbid states, but the task remains to be carried on, and perhaps solved, by the methods of the laboratory along lines which our clinical experience will indicate as necessary. Experimental methods may offer us the proof of a truth which clinical observation has already confidently recognised. Every Arctic explorer, for example, knew of the necessity for certain ingredients in the dietary of his shipmates. Gowland Hopkins has given the reason of the ancient experience in terms of vitamins. On a large scale among our troops in Mesopotamia the application of this new knowledge received the clearest illustrations. Among the Indian troops an absence of "C" vitamin involved 20,000 men in an attack of scurvy; and among the British troops an absence of "B" vitamin caused a heavy incidence of beri-beri. Had such occurrences taken place at the time of the South African war an explanation, true in essentials, would no doubt have been forthcoming: but there would have been no approach to the precise and accurate and demonstrable explanation which the work of Gowland Hopkins now allows us confidently to offer. It may be that we expect too much at first from laboratory methods. One of the new weapons put by them into our hands is that of vaccine therapy. No one can deny the occasional value, and at certain times the incomparable value, of this procedure; nor can any deny the grave disappointments which have so frequently attended its adoption. The hypothesis upon which it is based is probably very incomplete and many new aspects of a great truth remain to be discovered. But so far as focal infections are concerned our trust is still in operative treatment. The great triumph of vaccine therapy is in prophylaxis, which is difficult to measure in the individual case but easy to recognise in the mass. The complete record of the incidence of enteric fever in our own army, and in other armies in the last war, is evidence enough to convince the most sceptical.

EXAMPLES: CANCER AND TUBERCLE.

At this moment there are laboratories all over the world engaged in cancer research. The quest is for the cause of cancer. We do not know whether a micro-organism is sometimes, or never, or always, the agent: whether a habit of body, or a congenital disposition, or a mode of life contributes something to a larger causative influence. We do know that repeated minor insults to certain surfaces will produce a local response which, though not at first cancerous, makes haste to become so. If the cause of cancer is discovered we may learn how to prevent cancer, or even be brought to realise that there is a method of cure which directly depends upon our knowledge of the cause. But let us never forget that we already know how to eradicate cancer from almost all the parts of the body in which it commonly occurs. Nothing is more certain in clinical experience than this: that cancer, whatever its occult nature may be, is in truth a local disease in the first instance; that it

remains a local disease for periods which are sometimes short and sometimes very long, and that if then treated by operative methods upon a plan conformable to modern notions the disease is completely and permanently eradicated. The unending difficulty is to obtain access to the disease while it is still in the local stage. This, I venture to assert, imposes a new and larger duty upon the profession of medicine, the duty to enlighten the public as to the early symptoms and signs and to make it a matter of common knowledge that cancer is not, as everyone supposes, a disease from whose immediate or recurrent ravages there is no escape. We must broadcast the truth that, with few exceptions, an early operation for any cancerous disease is attended by the slightest risk, if, indeed, by any, and may confidently be expected to confer a permanent immunity from a return of the same disease. We do not know the cause, or causes, of cancer, but we do certainly know how to "cure" it, if only early opportunities are vouchsafed to us.

We most gratefully pay our tribute to Koch for his discovery of the tubercle bacillus. A knowledge of the existence of this organism, of its properties, of its causative influence in those "strumous" diseases whose exact nature was formerly unsuspected is all to the good. But our therapeutic power has not been increased by our recognition of the existence of the bacillus. No chemical attack made upon the bacillus while in the living body can destroy it, and the extent to which, if at all, we can augment the defensive powers of the body by any vaccine therapy is quite uncertain. The measures we adopt in the treatment both of the medical and of the surgical forms of tuberculosis are really independent of our acquaintance with the properties of the bacillus; they are measures which clinical experience little by little has indicated and improved. In other diseases, as in tetanus and in diphtheria, our therapeutic efficiency depends almost entirely upon the knowledge of their specific bacterial origin. All the efforts of all of us in league together are therefore necessary in our struggle against every disease, and we must surely base our strength not less upon the methods of the father of the inductive sciences, Hippocrates, than upon Galen, the father of the experimental method.

FEEDING OF THE ABNORMAL BABY BY THE SO-CALLED TRUBY KING METHODS.

A REVIEW OF THIRTY-NINE CASES.

BY MILDRED M. BURGESS, M.D. LOND.

THE object of this paper is to endeavour to show that however reasonable and scientific the theory that the formula of a baby's feed should bear a close analogy to that of human milk, it fails in many cases in its practical application, particularly in the abnormal baby. After a considerable experience in percentage feeding, I am forced to the conclusion that there is something more in human milk than is expressed in its percentage formula and caloric value, and that until we find a fat that can be tolerated by the infant we are doing incalculable harm to the infant population by insisting on a strict adherence to percentage feeding.

The 39 cases described below passed through the infants' ward of a babies' dietetic hospital during 1923. The remaining cases in the ward are not considered for various reasons; some were non-dietetic cases, some prematures, some on a new dried milk, in some the stay was too short for a satisfactory test, and some died from causes other than dietetic.

This paper contains: (a) A brief description of the methods adopted; (b) a summary of the cases under observation; (c) criticisms and deductions drawn from the results of the treatment.

Methods of Feeding Adopted.

The treatment (feeding) was carried out as closely as possible to the routine methods taught by the advocates of the system, and we had the advantage of a nursing staff trained in these methods. In every case the cause of admission was nutritional or dietetic—e.g., wasting, not getting on, screaming, sudden weaning, dyspepsia, or difficult feeding. In the majority of cases not one, but many of the above troubles were present. On admission the baby was weighed and a food chosen from one of the formulæ given below (usually H.M. III.) with no added fat. The amounts were regulated by a comparison with the previous feeding (if known) and by a consideration of the baby's theoretical food requirements. If the stools were unsatisfactory a dose of castor oil was given.

*Formulæ.**H.M. III. (New Formula).*

	Sug.	Fat.	Prot.
Milk, 8 oz.

Water up to 30 oz.			

P.c. comp. = Percentage composition. Cal. = Caloric.
N.a.f. = No added fat. Tsf. = Teaspoonfuls.

Orange or lemon juice was given daily and an abundance of plain boiled water.

Value of Boiled Breast Milk.—Breast milk was resorted to when all modifications failed, or if a baby became very ill. It was given in 19 of the 39 cases. An interesting point emerging from this analysis is the value of boiled breast milk. The milk was taken from healthy mothers at lying-in hospitals and to render it sterile it was boiled. It was given in the bottle added to the milk mixture. A curious fact is that the boiling seemed to have no deleterious effect on its value, thereby rather contradicting our previous opinion that one of the chief advantages of breast milk is that it comes straight from the mother to the child unaltered by sterilisation. In the majority of cases a few ounces only were given in the 24 hours, the "dose" being almost medicinal in some cases, and yet in a very large number of cases the effect on the child's digestive organs was rapid, satisfactory and permanent. In some cases, after only a few days' supply of breast milk, fat could be borne where previously it could not be tolerated. Whether some risks are not attendant on its use is another matter.

Ordinary cases were put on to H.M. III. (old formula), plain or peptonised. More difficult cases had Ideal milk, and a few were given whey and milk. Dried milk was used in a few cases. The ideal was to grade all modifications gradually on to H.M. III.

After 6 months of age Bengers' food was given in some cases, but the babies were graded off this before they were discharged.

There is no indication that any particular food was responsible for the breakdowns, although cow's milk was found to be rather more difficult of digestion than Ideal. Ideal was rarely used at the start, but after a breakdown the baby was sometimes put on to this.

The fat was given in the form of cod-liver oil emulsion (50 per cent.), prepared by a Grimsby firm. The amounts introduced started with 1½ oz. in the 24 hours, divided as nearly as possible between each feed, and the increases were made by 1½ oz. (sometimes 1/6) at intervals of a varying number of days. Not more than 1½ oz. was given in the 24 hours. When a breakdown occurred, as was shown by relaxed, curdy stools with or without vomiting, the fat was omitted or reduced, but as soon as the stools became normal again the fat was reintroduced, beginning with the smallest amount.

I am of opinion that in these cases the "curds" passed in the stools were invariably fat and not protein. They were soft and easily smoothed out. These so-called "curds" sometimes occurred even when the baby was on a fully peptonised or pancreatised food.

The baby was weighed twice weekly, and the actual caloric value of the food given, compared with its theoretical caloric value, was worked out each week. The temperature, pulse-rate, and respiration-rate, the number and consistence of the stools, and vomiting (if present) were recorded daily, and a note made of the amount of fat that was being given in the 24 hours. The careful records kept have made this analysis possible. The nursing was excellent, the handling and hygienic management of the babies were beyond criticism, and the enthusiasm and devotion of the nursing staff deserve the highest praise.

Principles of Treatment.

The general principles of the treatment are: (1) The percentages of the elements in the feed must be known, and such percentages must approximate to those of human milk; (2) the actual caloric value of the feed should approximate to the theoretical caloric requirements of the baby, although in marasmic babies the actual caloric value may be raised up to half as much again as the theoretical. The percentages in cow's milk were brought to those of human milk by dilution with water, the addition of fat in the form of cod-liver oil, and milk sugar or dextri-maltose. The actual and theoretical caloric values were worked out by means of a series of special tables.

Analysis of 39 Cases.

Uninterrupted recovery	3
Did well but fat had to be omitted or reduced	6
Broke down on fat once	10
" " twice	6
" " three times	3
Might have done better under other treatment	6
Died	5

*CLINICAL RECORDS.**1. Cases that made an Uninterrupted Recovery.*

No. 22.—M., aged 2 months. Admitted for losing weight. Put on to Cow and Gate (modified), graded to H.M. III. Fat increased from 1/12 oz. on 5th day to 7/12 on 30th day. Gain in weight, 9½ oz. in 31 days.

No. 30.—M., aged 7 months. A very bad home; admitted for wasting. On H.M. III. Fat increased from 1/12 to ½ oz. on discharge. Gain in weight, 13½ oz. in 21 days.

2. Cases that did Well but Fat had to be Omitted or Reduced.

No. 6.—M., aged 5 months. At first put on to Ideal, then pancreatised H.M. III., and later H.M. III. and barley-water. Admitted for wasting. Had diarrhoea and vomiting from 18th–22nd day and fat reduced. Otherwise he made continuous progress. Fat was raised from 1.4 per cent. to 2.6 per cent. and reduced to 1.4 per cent. on 19th day. It was raised to 3.4 per cent. by 54th day. Gain in weight, 5 lb. 7 oz. in 170 days.

No. 42.—M., aged 3 months. Fat introduced on 4th day and increased till 18th. Breakdown occurred from 11th–18th day. Breast milk had to be given from 13th to 17th day owing to loss in weight, relaxed stools and slight vomiting. Great improvement noted subsequently when food increased,

thereby raising caloric value and percentage of protein. Gain in weight, 1 lb. 4½ oz. in 55 days.

No. 29.—F., aged 3½ months. Fat introduced 1st day. Partial breakdown 7th–37th day. Stools were frequent, greenish, and relaxed till fat reduced from 1 oz. to ½ and again to ¼ and a higher percentage of milk given in the mixture, thus increasing the percentage of protein. Gain in weight satisfactory throughout, 1 lb. 9½ oz. in 53 days.

No. 43.—F., aged 5 months. Fat introduced 8th day and increased every few days till 33rd day. Breakdown occurred 29th–37th day. Fat taken out 34th day, reintroduced on 40th day. Admitted for vomiting and put on to diluted feeds. Fat undoubtedly increased too rapidly. Gain in weight, 8½ oz. in 47 days.

3. Cases that Broke Down on Fat Once.

No. 13.—M., aged 4½ months. Stools normal on admission; fat introduced on 5th day and increased rapidly up to ½ oz., although weight satisfactorily increasing, and an indication noted in stools that breakdown might occur. Fat was not omitted till six days after the stools became bad. After 29th day fat reintroduced but stools became relaxed again and vomiting occurred occasionally. On 52nd day food was increased and again on 75th day and fat was borne well. Improvement noted after the baby was 6 months old. Gain in weight, 3 lb. 15½ oz. in 108 days. If fat had been introduced more slowly, probably no breakdown would have occurred.

No. 34.—M., aged 3½ months. Fat introduced 4th day and increased on 7th. Breakdown 5th–16th day. Fat taken out 15th day, reintroduced on the 29th and increased every few days till 64th day. Stools normal on admission. After the breakdown stools did not become normal and occasional vomiting occurred, although weight improved. Later satisfactory progress was made till 60th day, when fat increased to 1 oz. (although 5½ oz. gain in weight since last weighing) and vomiting recurred. A further increase to 1 1/12 oz. caused three large vomits. Till discharge there was a tendency to vomiting and food was left. This is a case where more fat was introduced, although weight was already on the increase. Gain in weight, 2 lb. 9½ oz. in 89 days.

No. 41.—F., aged 5 months. Fat introduced 1st day. Breakdown 1st–9th day. Fat taken out 3rd day, but reintroduced on 15th and increased every few days till 57th. Stools frequent with curds till 6th day, then less frequent but curdy till 9th day, when food increased; 16th day food increased again. On 25th day grading to cow's milk from Ideal started and by 48th day cow's milk entirely substituted and food increased. Owing to increase in fat taking place on 56th and on 57th day, stools became relaxed and fat was reduced on 60th day. On the whole this baby stood fat well, but was 6 months of age after 37th day. The gain in weight was 8½ oz. in 63 days.

No. 40.—F., aged 6 weeks. Fat introduced 9th day and increased on 13th. Stools unsatisfactory till 28th day. Fat not taken out till 17th day. Reintroduced 33rd day. Although stool relaxed and curdy with mucus from admission till 9th day, fat was introduced. Breakdown continued a considerable time after fat taken out and was only cured by partial breast-milk feeding on 28th day, which was continued till 32nd day. After this baby improved rapidly. This case shows the value of even small doses of breast milk. Gain in weight, 13½ oz. in 45 days.

No. 14.—F., aged 4½ months. Fat introduced on 6th day and increased daily till 13th. Breakdown 12th–24th day. Fat taken out 15th day. Reintroduced 26th day and increased till 47th. Stools unsatisfactory from 33rd to 54th day, so no further increase made till 60th day. Stools normal or constipated till fat introduced; after breakdown not satisfactory till fat out. Stools relaxed and curdy again after reintroduction of fat till baby 6 months. Food pancreatised, then fat stood well. This baby broke down when protein percentages and actual caloric values were low. Gain in weight, 2 lb. ½ oz. in 103 days.

No. 24.—F., aged 11 weeks. Fat introduced 4th day and increased every few days till 27th. Days of breakdown 5th–11th, and again 33rd–45th. Fat not taken out till 43rd day. Normal stools on admission. After the first breakdown stools righted themselves when food increased. Ideal milk was graded to cow's milk on 19th day and the amount increased 33rd day. Fat was increased although baby was putting on weight rapidly, having gained 13½ oz. in nine days (19th day to 28th). An increase in the amount of food was ordered on 33rd day although the stools had been relaxed and greenish on 31st day. A large vomit occurred on 38th day and breakdown followed. Recovery was rapid after fat stopped and the milk was boiled. On reintroduction of fat vomiting recurred and fat was not being taken well when discharged on 54th day. Gain in weight, 2 lb. 2 oz. in 54 days.

4. Cases that Broke Down on Fat Twice.

No. 25.—F., aged 10 days. 1. Fat introduced 8th day, increased on 10th. Breakdown 9th–15th. Fat taken out

11th day. 2. Fat reintroduced 19th day. Breakdown 22nd–35th day. Fat taken out 35th day. Fat reintroduced 40th day. Increased on 42nd, but baby discharged on 47th day. Twin. Admitted with curds in stool and mucus occasionally. Milk mixture changed to milk and whey mixture on 6th day. Milk then peptonised. After second increase of fat seven stools passed and food was changed to Ideal and fat taken out on 11th day. Breast milk introduced on 13th day. By 16th day stools lessened and improved. From 20th–24th day some vomiting occurred and stools became curdy again on 22nd day. After fat taken out the second time, stools normal for five days (to 41st day), but from 42nd to 51st day stools relaxed with curds and on 45th and 46th day the baby had large projectile curdy vomits. Probably had baby remained in, fat would have had to be omitted again. Gain in weight, 1 lb. in 47 days.

No. 31.—M., aged 3½ months. 1. Fat introduced 4th day and increased on 6th. Breakdown 5th–17th day. Fat taken out 13th day. 2. Fat reintroduced 19th day and increased every few days to 44th day. Breakdown 48th day. Fat taken out 48th day. After effect of ol. ric. stools became normal by 4th day. In spite of gain of 7½ oz. fat was introduced. After first breakdown stools continued normal till fat reached 1 1/12 oz. in 24 hours on 44th day. On 48th day vomiting started and an acute attack of diarrhoea and sickness supervened. Fat was taken out again and other methods adopted with satisfactory results. On day of discharge (56th day) 1/12th fat again introduced and he was discharged on this amount. In this case the rapid increase in fat led to trouble. Gain in weight, 1 lb. 3 oz. in 56 days.

No. 45.—M., aged 6 months. 1. Fat introduced 5th day and increased up to 14th day. Breakdown 15th–20th day. Fat taken out 17th day. 2. Fat reintroduced 27th day and increased up to 51st day. Breakdown 53rd–63rd day. Reduced 59th day. Marasmic baby. Stools normal on admission and remained so for 14 days. From 15th to 18th day baby had attack of diarrhoea and vomiting, necessitating the introduction of breast milk. Stools became normal again. After five days on breast milk, Benger's given with satisfactory result, but from 38th–90th day no increase in milk given and caloric value only increased by introduction of fat. Gain in weight, 15½ oz. (slightly over 2 oz. per week) to 57th day. The increase in fat on 51st day started a breakdown on 53rd day lasting till 63rd day. On 88th day the baby was transferred to Toddlers' Ward. He made great progress after this. Gain in weight, 1 lb. 2½ oz. in 82 days.

No. 49.—F., aged 5½ months. 1. Fat introduced 1st day. Breakdown 4th–32nd day. Fat reduced 11th day, taken out 18th day. 2. Fat reintroduced 36th day and increased up to 63rd day. Breakdown 64th–72nd day. Fat taken out 68th day. Admitted for wasting, reported constipated. Stools normal three days and then became curdy, relaxed, and mucus passed. Diarrhoea and vomiting from 14th to 18th day. Stools bad till 32nd day and vomiting recurred on 36th day when fat was introduced again. Stools became unsatisfactory and some vomiting occurred. Gain in weight, 1 oz. in 25 days. Food was increased by 5 oz. in the 24 hours on 61st day and fat increased on 63rd day, with result that a breakdown occurred necessitating introduction of breast milk for two days and fat was taken out. Fat in another form was introduced on 77th day with satisfactory results. Gain in weight, 8½ oz. in 88 days.

5. Cases that Broke Down on Fat Three Times.

Nos. 19 and 20.—F., aged 3 weeks. (1) Fat introduced 5th day and increased on 8th. Stools curdy with mucus from the start to 7th day, then improved, but became bad again after increase in fat. Fat taken out 9th day. (2) Fat reintroduced 11th day and increased on 26th and 32nd day. Stools unsatisfactory and vomiting started on 31st day. Fat was taken out on the 40th day. (3) Fat reintroduced on the 41st day and increased on the 42nd and 45th day. A bad breakdown occurred from the 44th to 51st day and fat was taken out again on the 48th day. Fat was reintroduced again on the 53rd day and increased till discharge on the 61st day, when the stools were normal but there was some vomiting. Gain in weight, 11 oz. in 61 days.

No. 33.—F., aged 2½ months. This was a normal baby admitted for sudden weaning. Stools normal on admission and continued so for nine days. (1) Fat introduced 4th day and increased on the 6th. Breakdown 10th to 19th day. Fat taken out on the 12th day. (2) Fat reintroduced on the 24th day and increased up to the 39th day. Breakdown 40th–51st day. Fat taken out on the 42nd day. (3) Reintroduced on the 44th day and taken out again on the 52nd day. In spite of watery and relaxed stools fat was reintroduced again on the 62nd day and increased every few days up to the 82nd day. Diarrhoea with "curds" and mucus supervened on the 86th day and fat had to be taken out again. Breast milk was resorted to from the 95th to 108th day, and the stools became normal again. This baby had cow's milk and water, Ideal and partial whey feeding, but there appeared to be no difference in the stools as long as fat was introduced. Gain in weight, 1 lb. ½ oz. in 115 days.

6. Cases that Might have Done Better under other Treatment.

No. 26.—F., aged 10 days; weight 3 lb. 14½ oz. Stools unsatisfactory from admission. Relaxed, frequent, curdy stools with mucus till breast milk given 17th day: very little difference with or without fat. This baby had breast milk on and off from 17th to 36th day, after which stools improved and Ideal milk was given. The food requirements of this baby were never met except with breast milk. Gain in weight, 9½ oz. in 48 days.

No. 48.—F., aged 2 months; weight 6 lb. 15¼ oz. Stools normal on admission. Fat introduced on 4th day and taken out on 6th. Fat reintroduced on 12th day and increased up to 23rd day. A serious breakdown occurred starting with vomiting on the 17th day and the baby was put on to breast milk with some improvement. With the increase of fat, however, the baby became very ill and fat was taken out on the 27th day. From the 28th to the 49th day the baby became rapidly worse and was apparently dying. Weight was 5 lb. 15½ oz. on 51st day, when I abandoned these methods altogether and gave a food with a higher percentage of sugar. Her condition improved, and later on breast milk was added which later was changed to a milk and whey mixture and again to milk and water with a different fat. Weight, 8 lb. 8½ oz. on discharge on the 144th day.

No. 56.—F., aged 3 months; weight, 8 lb. 2 oz. This child had fat intolerance from the start. Three attempts made to introduce fat failed. Breast milk was given for two periods, but the baby had lost 1 lb. 9½ oz. by the 67th day. In consequence of the baby's inability to take fat the food requirements were never met till Benger's food was added. Practically all gain in weight occurred after this.

7. Cases that Died.

No. 36.—M., aged 2¼ months; weight 8 lb. 14 oz. Admitted for dieting. Four out of six previous children dead. The two living were brought up on Nestlé's. Stools bad from the first and vomiting supervened on 22nd day. This was a case where fat could not be introduced and no other attempt was made to raise the caloric value of food. After 17th day breast milk was added. Baby died 54th day.

No. 44.—F., aged 3½ months; weight 8 lb. 8 oz. Admitted for dieting. Stools normal (except on 2nd day) till 9th day. Fat introduced 3rd day and increased twice. After increase in fat on 8th day three vomits occurred, and on 11th day diarrhoea and vomiting supervened. Temp. rose. After fat was taken out stools became normal for a few days and weight increased. Food was increased on 23rd day and stools became relaxed again with vomiting on 26th and 27th days. In spite of this, fat was introduced again on 28th day. Temp. went up again and diarrhoea and vomiting followed. Baby collapsed and died on 38th day. This case shows that the introduction of fat is not without risk.

No. 53.—M., aged 3½ months; weight, 9 lb. 10½ oz. Admitted for vomiting and diarrhoea. Frequent vomiting after admission for three days relieved with bismuth. Normal stools and no sickness on sixth day, weight increasing. Fat introduced 7th day. Vomiting (six vomits) started again after introduction of fat on 9th day, and in spite of this fat increased on 11th day. Diarrhoea started and vomiting increased; weight dropped and stools did not improve and baby became collapsed. After breast milk, stools improved and vomiting ceased by 27th day, but baby died on 34th day. Another case showing the risk of fat in a baby with digestive disturbance.

Criticisms.

(1) *On the Percentages Taken as Representative of Cow's and Human Milk.*—The feeds are based on the assumption that the average composition of human and cow's milk are as follows:—

		Proteins.	Fats.	Sugar.
Human		1.5-1.25 %	3.75-3.5 %	7-6.5 %
Cow's		3.3 %	3.5 %	.5 %

A series of analyses of the certified Grade A milk used in preparing the feeds gave an average as follows: fat, 4.3; protein, 3.5; lactose, 4.9. In some samples there was a difference of over 1 per cent. in fat, a difference which alters the whole of the calculations on which the feeds are prepared.

The percentages of human milk given in text-books approximate closely to the figures given above, but they are taken in most cases from nursing mothers in countries other than our own. I have seen a good many analyses of human milk from British nursing mothers, though perhaps hardly sufficient to form a

working basis, but the percentages were very different from those given above, especially as regards the protein.

(2) *On the Method of Introducing and Increasing Fat, even when the Baby Shows Fat-Intolerance.*—Of the 39 cases, 25 broke down on fat: 16 once, 6 twice, 3 three times, and of those that died 3 out of 5 had diarrhoea or vomiting or both after the introduction of fat, and 3 out of 5 had normal stools before the introduction of fat.

The first question that will naturally be asked is whether the breakdown could not be attributed to causes other than the fat. What proof is there that the fat is responsible in all these 25 cases? The answer is that invariably one or more of three conditions was found—sometimes all—viz., (1) The stools were normal, there was no vomiting, food was taken well, and in some cases weight increased before the introduction of fat, and in the majority of cases no other alteration in diet was made at the time the fat was introduced. (2) The stools lessened in number and improved in consistence and colour when fat was taken out. (3) The same conditions recurred with each fresh introduction of fat or increase in fat. In a few cases the breakdown did not occur till some considerable time after the fat had been put in and increased, but in these cases also the removal of fat effected the cure.

Intolerance of fat is recognised by the advocates of this system, but they argue that if fat be persevered in long enough or a sufficient number of attempts are made to introduce it the baby will stand it in the end. Personally, I think the risk is too great, without a more careful consideration of the baby's symptoms and the weight chart, inasmuch as in a few cases the symptoms produced by the introduction of fat were not relieved when the fat was taken out, and the results show that it is easier to start an intolerance than to effect a cure. The removal of the cause does not always stop a gastro-enteritis.

Again, the fat appears to be introduced or increased without any consideration of the baby's symptoms. It is done because it is part of the system in order to bring the percentages of the elements to the standard of human milk (where the fat is about 3.5 per cent.) and to raise the actual caloric value of the food to that of the baby's theoretical requirements. Four-hourly feeding and no night feeds are the ideals aimed at. Without fat the quantity of "humanised" milk the baby can take for its age at these intervals does not give sufficient calories and the baby is on a "starvation diet" till fat is introduced and increased. For this reason as soon as the baby has settled down to its environment fat is introduced whether the baby is gaining satisfactorily without it or not, and the records do not show that the baby is invariably weighed before any increase is made in fat or food to see that such increase is desirable. It is again increased after a few days, although a warning may be given in the form of relaxed stools or curdy returns that the fat may not be suiting the baby. In a good many cases small amounts of fat were stood well, and probably larger amounts would have been tolerated and a breakdown avoided altogether had a longer interval elapsed between each fresh introduction. It seems particularly foolish to start fat in a baby sent in for vomiting, or in one with curdy relaxed stools, even when these symptoms are temporarily in abeyance. In many cases fat was borne well in babies over 6 months of age, and there seemed to be more difficulty when the protein percentage was low or when the caloric value of the foods was considerably below the baby's theoretical requirements.

Undoubtedly, too, fat was borne better when the food was pancreatised and the change to this at about 6 months of age often brought about a great improvement in the baby and gain in weight, but this tolerance may have been due to the child's age. After the breakdown was over and the condition of the baby as before (except possibly for loss of weight), the amount of fat reintroduced was the smallest amount the baby had started with. This is sound

treatment, but it was disheartening to find that the whole of our previous efforts in working up the fat had been felled at one blow, particularly when after the fat had been raised to 1 $\frac{1}{12}$ oz. the baby left hospital on $\frac{1}{12}$, or $\frac{1}{6}$ oz. only.

(3) *On the General Principles of the System.*—The same adherence to feeding by figures and the lack of scientific appreciation of the child's symptoms are noticed in the fact that an increase in the protein and sugar was never made beyond the human percentages although the baby was obviously crying out for one or the other of them. Nor was the food increased beyond a certain amount, nor the percentage of milk to water raised beyond a 1:1 mixture, although the baby was hungry, constipated, and not gaining in weight. When the percentages of protein and sugar had reached the limit prescribed and the actual caloric value of the food was half as much again as the theoretical, the only thing to raise the food in value was the introduction of fat, and if there was intolerance for this it meant that the baby must suffer from slow starvation. I fail to see why, if it is allowable to diverge from the percentages in fat, it is considered an infringement of their principles to do so in respect of sugar or protein.

No difference in the methods appeared to be made in hot or cold weather; the theoretical caloric requirements were considered to be the same summer or winter, nor was any allowance made for an energetic baby who naturally required a food of a higher caloric value than a lethargic one. Further, normal and abnormal babies are treated on the same principles. I think the failure to recognise that the abnormal baby cannot respond to the same line of treatment as the normal one is serious, particularly with regard to its intolerance for fat. Far more so is the attitude taken by some (possibly over-zealous) advocates of these methods, that all cases must be treated on these lines and no other. To use their own words: "They would die sooner under any other treatment."

Deductions.

1. An abnormal baby has a great intolerance for fat. This is no new doctrine.
2. It is impossible to feed all abnormal babies on a percentage system if the percentages followed are those at present given for human milk.
3. It is unwise to risk the introduction or increase of fat in the food of an abnormal baby unless there has been no digestive disturbance for some considerable time, and not then if the weight curve is rising satisfactorily without it.
4. The caloric value of the food required by a marasmic baby is probably more than half as much again as its theoretical value, or, to put it another way, the same standard of feeding by caloric values cannot be applied when a baby is exceedingly below its average weight for its age, even when half as much again is allowed.
5. It has not been proved that the so-called Truby King methods of percentage feeding is the best and only substitute for breast milk. This is evidenced as follows: (a) That in many of the cases sent out in good health, resort had to be had to breast milk to put them on the right road. (b) That gain in weight and general improvement which was first obtained was lost through breakdowns during the course of the treatment, and the total gain in weight was less than would have been otherwise obtained. (c) That some babies actually suffered in consequence of the treatment.
6. The difficulty of ascertaining a baby's power of absorption. This is a vital point, for it may be found that a baby fed on an artificial food, as cow's milk, needs to be given a higher percentage of some of the food elements because in this form he can assimilate only a certain proportion of the whole, rejecting a great deal which is passed in the stools; whereas in the form the elements are presented in human milk, although in lower percentages, practically the whole may be assimilated.

A CASE OF CEREBRAL ABSCESS COMPLICATING ABSCESS OF LUNG:

OPERATION AND RECOVERY.

BY SEYMOUR BARLING, C.M.G., F.R.C.S. ENG.,
SURGEON TO THE GENERAL HOSPITAL AND TO THE
CHILDREN'S HOSPITAL, BIRMINGHAM.

DISTANT foci of suppuration in any part of the body may occasionally be complicated by cerebral abscess; and it has long been recognised that suppuration in the lung or pleural cavity is especially prone to be so complicated. As early as 1815 Richard Powell¹ records a case of empyema accompanied by an abscess beneath the corpus callosum, though he did not appear to relate the two conditions. Admittedly the complication is rare, yet the total number of cases recorded is not inconsiderable. Thus Schorstein² in 3700 autopsies at Brompton Hospital finds abscess in conjunction with disease of lung or pleura to be the cause of death in 17 cases, and further he finds such abscesses the cause of death in two cases in 10,000 autopsies at the London Hospital. In addition to these 19 cases, of which he gives details, he analyses 50 others taken from literature. His paper appears to include all cases recorded at the time of its publication in 1909. Clayton,³ after recording a case of his own, analyses a series of 58 cases which are on record, some of them having previously been summarised by Schorstein. From both papers it would appear that bronchiectasis occupies an outstanding position as the primary lesion; Schorstein states it is so in 38 of his 69 cases, empyema being second with 15 cases, the 16 remaining cases being due to gangrene or abscess of lung, tubercle, acute pneumonia, or foetid bronchitis.

Localisation and Distribution.

The abscesses are nearly always in the hemisphere, and often near the cortex, but have been found in cerebellum, medulla, or pons. Schorstein points out that in his collected cases the left side of the brain is affected more than twice as frequently as the right; and if the cases of multiple abscesses are excluded and the single abscesses alone considered the predominance of left-sided abscesses is more than 3 to 1. Whilst admitting the pathological obscurity surrounding the association of brain abscess with lung disease (where no other abscess is found in the body) he considers that this predominance of the left-sided abscess is in favour of the embolic origin of the infection, and compares it to a like preponderance of left-sided brain infarcts in valvular disease of the heart. The occasional occurrence of epileptiform convulsions on irrigating the pleura in cases of empyema, as noted by Finlay⁴ and Caley,⁵ is certainly suggestive of this embolic origin, though in no case has the embolus been actually found, although death may occur within a short time of the onset of the convulsions.

The abscesses are sometimes single, sometimes multiple. Metastatic brain abscesses in general appear to be more commonly multiple—according to Gowers⁶ they are so in 61 per cent. of cases—but in the group of pulmonary cases the single abscesses appear to predominate. Of 51 of Schorstein's cases in which accurate information was available 62 per cent. were single and 37 per cent. multiple.

Symptoms and Clinical Course.

The clinical course and symptoms of cerebral abscess arising in association with pulmonary disease do not differ essentially from cerebral abscess arising from local causes such as traumatic and otitic cases, if we remember that the latter are generally single and the pulmonary cases often multiple. Also the sub-normal temperature and slow pulse may be masked by the primary lesion. Signs of rapidly increasing intracranial tension with slow cerebration and great dulling of the mind are most characteristic in many cases, together with localising fits or paresis appropriate to the area involved.

The progress of the abscess is usually rapid, and not a few rupture into the ventricle or on to the surface. In the group recorded by Schorstein death occurred on an average ten days after the onset of the cerebral symptoms, and the duration varied between three and 28 days. Some of the abscesses are encapsuled, most are not; the encapsuled abscesses are probably of some weeks' duration at least, judging by the records of encapsulation of traumatic cerebral abscess in which the date of onset is accurately known. Such encapsuled abscesses may be entirely latent; this, however, is probably rare, and in the majority of cases the course is an acute one.

Treatment.

The only treatment offering the possibility of cure is drainage of the abscess. This has been carried out in a few cases, but I can find no record of a recovery previous to the case given below. In a case of Barnard's the patient lived seven days after evacuation of the abscess. The debilitated condition of the patient, the difficulties of localisation, which are undoubtedly greater than in the case of traumatic or otitic abscess, the multiplicity of the lesion in more than one-third of the cases, and the acute course of the abscess are all against a successful result. At the same time, when the post-mortem findings in a number of these cases are studied, one cannot help feeling that some might have been cured had they been operated on. Such intervention must, in view of the rapid course these cases run, be carried out at the earliest possible moment after the onset of the localising symptoms.

Clinical Record.

A. S., male, aged 48, was admitted to the General Hospital, Birmingham, August, 1923. He stated that on two occasions during the last fortnight he had had attacks of seeing double when at work, and recently had frequently run into people and objects approaching him on the left side. In May, 1918, he had a severe attack of pneumonia and was ill on and off till October of that year; he was treated at home at first but admitted to hospital in July, 1918, with a diagnosis of lung abscess. The diagnosis was not established, however, and he was sent to a convalescent home for a time. He returned to work, but after a short time he contracted influenza in November, 1918, and was again ill for a month. He once more returned to work, but was very weak and ill for the next six months, coughing up a large quantity of offensive sputum daily and suffering from sweats with much loss of weight.

In July, 1919, he was again admitted to hospital with cough, emaciation, and offensive sputum, and in addition he had abdominal distension with vomiting and tenderness in the lower abdomen. Phthisis with tuberculous peritonitis was suspected. No T.B. could be found, and the von Pirquet test was negative. He gradually improved and left hospital. A month later he entered a neighbouring hospital, being then very wasted and anæmic, and complaining of pain in the right chest and right abdomen. His fingers were clubbed, and breath sounds and expansion of the right lower chest were diminished. The sputum was offensive, and varied from 4 to 14 oz. daily. The right lower pleura was explored, but nothing but adhesions found. Shortly after this he had severe abdominal pain with rigidity and vomiting and a temperature of 103° F.; these symptoms abated and he gradually improved. Some months after leaving hospital he returned to work, but continued in indifferent health till seen in 1923. During these three and a half years he expectorated a considerable quantity of offensive sputum daily, stating that he "vomited" it up painlessly two or three times a day. The daily amount was tending to diminish recently. His reason for again seeking advice was the onset of the ocular symptoms a fortnight previously.

Condition on Admission.—He was sallow and anæmic, his sputum was dark reddish-brown and most offensive, and averaged 10 oz. per diem. Elastic fibres were stated to have been found in it on one occasion, but this was not confirmed. The movements of the right lower chest were restricted and the infrascapular area was dull and silent. X rays showed a high immobile right diaphragm, the costophrenic sulcus being clear; the lower lobe was mottled, but there was no evidence of cavitation or abscess. There was weakness of the left hand and arm with a left extensor plantar reflex. Examination of the eyes showed the fundi to be normal with good visual acuity in each eye; left homonymous hemianopsia, with preservation of the macula on each side.

A single lesion in the right occipital lobe would account for the cerebral symptoms, and it appeared probable that it was secondary to the thoracic condition. With regard to the nature of this latter there was some doubt. The X ray picture was considered to point rather to bronchiectasis than to lung abscess, but the physical examination of the chest showed nothing distinctive of either condition. The expectoration of a large quantity of offensive sputum had, however, been present from almost the earliest days of his illness, and this had evidently been considered suggestive of lung abscess, which was the diagnosis on his first admission to hospital two months after the onset of the initial pneumonia. The possibility of a subdiaphragmatic abscess pointing through the diaphragm was considered in view of the history of peritonitic symptoms.

It was decided to operate on the thorax first, in view of the quiescence of the brain condition.

Thoracotomy (August 8th, 1923).—Through an oblique incision across the right infrascapular region 5 inches of the ninth and tenth ribs were removed just external to their angles. The two pleural layers were united by adhesions, and no empyema could be found. The lung was incised freely and a finger introduced in all directions. No cavity was tapped. The lung was cedematous, almost airless, and firmer than normal; a large tube was stitched into one of the tracks passing into the lung substance. The operation was done under gas and oxygen, and the patient was very bad during the short time he was anaesthetised, only being saved from flooding his other lung with the pus he was coughing up by being placed with his head much lower than his body.

Three days after operation the discharge from the lung wound became excessive and very offensive; coincident with this his sputum became less offensive and much diminished in amount. A month later his lung wound was granulating and the sputum consisted of about $\frac{1}{2}$ oz. of inoffensive mucus daily. By this time, however, his cerebral symptoms were much worse. Patient was dull, incontinent, with a low blood pressure and a furred tongue. The temperature was subnormal, pulse about 90, and he had lost weight considerably. The left hemiplegia was more pronounced, and he now had in addition a right extensor plantar reflex. The retinal veins were full but no neuritis was present. His condition was obviously desperate, but it was decided to try and tap the abscess. The patient was trephined below and behind the right parietal eminence. On enlarging the opening the dura was found to be tense, and was incised. On introducing a forceps inwards, forwards, and downwards pus was obtained at about two inches from the surface—about three ounces were evacuated and it smelt of *B. coli*. A tube was introduced through the centre of the flap and the latter replaced, with rubber drains beneath it radiating from the centre drain.

Great improvement in the patient's condition was noticeable in a few hours, and by the next day he was bright, intelligent, and was using his left arm, hand, and leg freely. The pus grew streptococci, staphylococci, and a coliform bacillus. Convalescence was uneventful, but the drainage-tube was not finally removed for a month, by which time the abscess cavity was obliterated and the tube track rapidly healed after the removal of the tube.

On examination of the eyes (Oct. 19th) the fundi were normal, there was a partial left homonymous hemianopsia, the upper part of the field recovering. Visual acuity, left 6/12, right 6/6. The lung wound by this time was healed and the patient's general condition was excellent. He still coughed up a few ounces of non-offensive frothy sputum each day.

Seen some months later the patient had a depressed area at the site of the cranial operation; the right lower chest posteriorly showed restricted movement and air-entry, a little frothy sputum was expectorated, and he was at work in better health than he had been for years.

Commentary.

The question of diagnosis of the exact condition in the lung was not definitely settled; it was almost certainly either a bronchiectasis or a chronic abscess, and the X ray picture was more suggestive of the former condition. The sudden increase of discharge the third day after thoracotomy with cessation of expectoration suggests, however, that a chronic abscess cavity unreached at operation suddenly established communication with the wound. Drainage of a bronchiectatic cavity or series of cavities would be extremely likely to give rise to a bronchial fistula—however, the lung wound healed without undue delay. No cavities were met with in the hurried exploration. Undoubtedly the thoracotomy should have been done under local anaesthesia—the general anaesthesia caused the patient grave risk of death by flooding with the large quantity of sputum coughed up—only the placing

of the patient in the head-down position prevented the swamping of the opposite lung. Attempts to empty the cavity beforehand had not been as successful as was anticipated.

Reviewing the whole case, it would probably have been wiser to have operated on the cerebral abscess before the lung condition, as by the time the patient had recovered from the thoracotomy he was almost in extremis from the intracranial pressure of the abscess. It was thought better at the time to deal with the causative condition first as the brain lesion then appeared quiescent. I was not aware at the time that the majority of such cases run a very rapid course, and although in the published records some of the abscesses must have been of some weeks' standing at least as they were encapsuled, yet Schorstein states that the average length of life from the onset of the cerebral symptoms was only ten days and varied from three to 28 days. The only reasonable hope, therefore, of successful surgical interference is to deal with the cerebral complication first.

ABNORMALLY LOW PULSE PRESSURES IN CASES OF NEUROSIS.

BY WILLIAM BAIN, M.D., F.R.C.P. LOND.,

AND

C. W. CURTIS BAIN, M.C., M.B. OXF.,
M.R.C.P. LOND.

THE normal limits of the pulse pressure may be taken to lie between 40 and 55 mm. of mercury. Increase of this pressure is found in several conditions. In senile arterial change the systolic pressure is raised, and the diastolic is lowered, with the result that the pulse pressure is increased. In hypertension, whether renal or not, the pulse pressure is nearly always increased in proportion to the height of the systolic, while in an uncomplicated aortic insufficiency the increase is striking, chiefly owing to the lowness of the diastolic, though elevation of the systolic often contributes. As Harris¹ has noted, increase of this pressure occurs also in Graves's disease associated with tachycardia; but any temporary emotion, such as that caused by examination, may in nervous subjects cause an increase in the pulse pressure by raising the systolic.

Decrease in the pulse pressure is not so common. It occurs in tachycardia, especially paroxysmal, in advanced mitral stenosis, and conditions of circulatory failure. No evidence has yet been forthcoming as to its presence in any other group of cases with normal pulse-rates.

Observations on 2000 General Cases.

Out of 2000 general cases in which the blood pressure has been taken by the auscultatory method on an average of four times each, 230 were found to present pulse pressures of 30 or under on one or more occasions. Cases which showed pulse pressures of between 30 and 40 were rejected as being doubtful. In very few cases was the pulse-rate over 100, nor were any cases of advanced mitral stenosis or of heart failure included. The blood pressure was taken in the sitting posture with the patient's arm resting on the desk.

Systolic Pressure in Mm. Mercury.

P.P.	85	90	95	100	105	110	115	120	125	130	135	140	N.C.
30		2	1	3	5	21	1	21		10		3	67
27		2		7	12	9	2	5	1	2	1	2	43
25	1		2	14	16	8		6	8	1	1		57
22	1	1	2	6		2	1	4	1	1			19
20		1		8	2	6	1	9	1			1	30
17			3	1	1	1	1						8
15		1		3		2							6
	2	7	8	42	36	49	6	46	11	15	2	6	230

P.P. = Pulse pressures.

N.C. = Numbers of cases.

Systolic and pulse pressures are shown. Diastolic pressures can be obtained by subtracting the pulse pressure from the systolic pressure.

From the chart it can be seen that the total range of the systolic pressures was from 85 to 140, but by far the greater number lay between 100 and 115. Where one case had several pulse pressures under 30 the lowest was taken. The ages of the patients ranged from 25 to 70, the majority being between 35 and 50.

These cases were grouped as follows:—

1. Neurasthenic, numbering 93. This group consisted of neurasthenics of all sorts, from constitutional neurasthenics to cases where dental sepsis or astigmatism contributed to the exhaustion of the nervous system. Apart from palpitation, usually of gastric origin, there were no cardiac symptoms.

2. Nervous, consisting of 64 cases. These cases, while not neurasthenic, were definitely neurotic, including many with marked vaso-motor disturbances. Some had few symptoms, and the neurosis might not have been suspected had the pulse pressure not been noted. One such case, a man of 26, weighing 16 st., said he was in perfect health, and merely wanted his weight reduced. The systolic pressure was 90 and the diastolic 70 (registered in this case by the Pachon). On being questioned he admitted that for the last two years he had suffered from marked depression.

3. Mucous colitis, of which there were 48 cases. Every case showing an abnormal amount of mucus in the stools was put in this group. The nervous phenomena associated with this condition are so well known that it was thought better to do so rather than divide them among the neurasthenics and neurotics.

4. Cases associated with some organic affection totalled 26. Some of these—e.g., rheumatoid arthritis cases, were suffering considerable pain. Three of them were in a state of anxiety about their condition. One man, otherwise normal, was faced with an operation for ureteric calculus. After showing three abnormal pressures he passed the stone into his bladder. Unfortunately, no further readings could be taken, as he was not examined again.

The treatment of cases of the first two groups was in general that of neurasthenia. They improved by general tonic treatment after the removal of any septic foci, the correction of errors of refraction, and the promotion of digestive efficiency. The pulse pressure, however, was a guide to the efficacy of the treatment. Constitutional neurasthenics, whose condition could only be alleviated, tended to show abnormal pulse pressures at the end of the treatment as at the beginning, while those in which it became normal invariably lost their symptoms and usually ended in recovery.

In the following examples the average interval between pulse-pressure readings was five days:—

1. Constitutional neurasthenic. M., aged 60:—

	1st.	2nd.	3rd.	4th.
Syst. ..	114	92	98	90
Diast. ..	90	70	70	65

This patient has been under observation for years. He improves under treatment, but invariably relapses under the stress of work at home.

2. Neurasthenic. F., aged 35:—

	1st.	2nd.	3rd.	4th.
Syst. ..	98	100	122	120
Diast. ..	78	80	92	80

This patient had lost 1½ st. in the previous two years. She gained 5 lb. during this period and lost all her symptoms.

3. Mucous colitis. F., aged 53:—

	1st.	2nd.	3rd.	4th.
Syst. ..	148	118	124	140
Diast. ..	100	90	100	88

The catarrh of the colon cleared up after four douches between the second and third examination, and she then made a rapid recovery.

Discussion.

Neurotic subjects are about equally divided in the matter of their pulse pressures. About half of them will always show high readings. In a few cases of obvious neurosis the pulse pressures are normal. The readings on the first examination always tend to be high through the emotional factor, and should be accepted with reserve. In some it is not until much later that the true pressure is revealed. The following is an example from an apprehensive neurasthenic in which the fourth and succeeding pressures are probably the true ones:—

F., aged 49:—

Syst. ..	138	124	112	100	105	105	124	120
Diast. ..	88	90	90	90	90	90	86	96

On the last occasion she said she felt quite well. There is little doubt that she will relapse at home.

The abnormally high pulse pressures have not been dealt with here, as other conditions have to be excluded before they can be accounted neurotic. No satisfactory means of differentiating between the two classes has yet been found, though the low ones seem in the main to be vagotonics. Acidity with flatulence is common, and cold extremities are not infrequent. As a physical sign a low pulse pressure has the advantage that it occurs in cases where the opposite might be expected. It is sometimes the means of revealing the presence of an otherwise obscure neurosis which the patient may be reluctant to disclose, and it is certainly a useful index of the response to treatment.

The cause of the condition must be related to a diminution in the cardiac output. This could be due either to a primary cardiac asthenia, or to defective filling of the heart. Apart from variable apical systolic murmurs, there was no evidence of any cardiac involvement. Electro-cardiograms in a few test cases showed normal curves. The quantity of blood entering the heart is determined by the effective volume in circulation. It could be influenced either by an alteration in the total volume of the blood, or by stagnation of blood in any of the venous or capillary reservoirs.

M'Dowall² has shown that in the cat in cases of low venous pressure near the heart following hæmorrhage, or the administration of alcohol, or the injection of histamine, section of the vagus will cause a further reduction in arterial pressure. He considers that there is a vago-pressor reflex under these conditions to prevent excessive lowering of the mean pressure. If this reflex is present in man in cases where the systolic is low, the result could be obtained by a raising of the diastolic, thus bringing about a small pulse pressure. This might particularly apply where the vagal influence was already predominating.

The vaso-motor systems of these cases are in a very unstable condition. Their pressures are liable to fluctuate largely from emotional and other causes. It is therefore unlikely that there is any alteration in the total blood volume. We would suggest that the probable explanation is to be found in some deficiency in vascular tone giving rise to inefficient circulation through the capillaries or venous radicles.

We desire to express our thanks to Prof. J. A. MacWilliam, of Aberdeen, for reading the manuscript and for helpful criticism.

Summary.

1. An analysis of 2000 general cases shows that 230 presented pulse pressures of 30 mm. of mercury or under.

2. In 90 per cent. this was associated with nervous phenomena, either neurasthenia or neurosis.

3. Return of the pulse pressure to normal was found to be an indication of improvement in the general condition.

4. It is suggested that lack of vascular tone causing stagnation of blood is the most likely explanation.

ANTI-CONSUMPTIVE THERAPEUSIS.

By R. HERVÉ, M.D.,

DIRECTOR OF THE SANATORIUM DES PINS AND OF THE STATION CLIMATIQUE DES ESCALDES.

SINCE the advent of treatment by artificial pneumothorax we are no longer helpless in the face of pulmonary tuberculosis and we are conscious of being frequently useful to our patients: Why is it, then, that this method, so fruitful in immediate and even definitive results, is yet so often disappointing? In my opinion the reason is, that, relying too much on the relief given to his patients by pneumothorax, the expert is apt to neglect the old rational therapy, which in the midst of more or less specific treatments has held its own for over 50 years—namely, hygiene and dietetics. To conclude from the often remarkable results of compression, as was frequently done, that consumptives with a pneumothorax could continue to live in town and go about their business, while neglecting the essential curative factors of rest and open air, is to disregard the whole character of the illness. At the present time, the doctrine of primary infantile infection being definitely accepted, the clinician when visited by a patient with active tuberculosis of the lungs, cannot lose sight of the fact that the affection revealed by his inspection is of long-standing origin. Long before the morbid manifestation the organism was impregnated with tuberculous poison. With or without local lesions, the subject had reacted, sometimes unawares, against the attacks of the affection. Tuberculosis of the lungs (the most frequent manifestation), tuberculosis of the glands, of the joints, or of the bones, represent merely pitched battles in an ancient war. Can we therefore expect that by temporarily suspending the functions of a lung we may, at a stroke, radically suppress all traces of tuberculosis and restore the normal physiological functions to debilitated organs? To this I can give an answer based on observations in two of my cases which were published in the *Presse Médicale* (No. 75, Sept. 19th, 1923)—cases of which I have since had numerous other examples—of tuberculosis progressing in a collapsed pocket in the lung in spite of an appearance of perfect compression. Secondary manifestations are also liable to occur after the collapsed lung has dried and healed up—namely, meningitis, bacillary nephritis, epididymitis, peritonitis, and so forth.

The fact is that the hygienic-dietetic treatment, combined with a well-ordered rest cure, is an essential and is all the more efficacious after the Forlanini application. By "hygiene" I mean the open-air treatment, which must be carried out without remission day and night. Fresh air, like a benign spectre, must accompany the patient throughout the daily routine indoors or outdoors. By "dietetics" I mean that form of treatment which, in spite of the reduced importance which we now give it, nevertheless plays an important part in establishing a cure. In prescribing it the attention and wisdom of the doctor will be daily put to the test, as much to stimulate and regularise the digestive functions of the patient as to protect him against the dangers of untimely over-feeding. A further important factor in treatment is climate, and the right choice of climate is by no

² M'Dowall, R. J. S.: *Journal of Physiology*, 1924.

means easy for the average practitioner to decide, and yet all specialists know how, on one hand, a well-chosen climate can influence the evolution of the illness and how, on the other hand, to send a patient with congestion or hypertension to the mountains may be disastrous.

To supplement the hygienic-dietetic treatment, I would add heliotherapy, now of proved efficacy, thanks to Rollier's works, in the treatment of tuberculosis of the bones and glands, although its virtues are still questioned in the treatment of pulmonary tuberculosis, in spite of the work¹ which I have been publishing for over ten years, following Malgat in France and preceding the later studies of Oelsnitz, Bernère, Gassul, and Liebe.

Heliotherapy, if applied in due time, confirms and consolidates the results obtained by the open-air treatment. What rest and climate alone cannot always effect—namely, return of the appetite,

cure which, in spite of the official disfavour in which it lies to-day, has still numerous successes to its credit. For long it was usual to rely on hydro-mineral treatment for the treatment of tuberculosis of the bones, and its efficacy was hardly questioned until first the marine cure, then mountain-heliotherapy came into medical favour.

Why do we not associate these various elements of treatment, when Nature offers them to us accumulated in one locality? I saw at Escaldes a patient with coxalgia and multiple fistulas of long standing who was recommended for amputation whilst showing extension and activity of the suppurating foci. A localisation in the lung appeared, and if this advice had been followed the outcome would have been certainly fatal. Yet after eight months' sun and bathing treatment all the fistulas closed. The patient left the establishment on his feet and could walk two miles. Not only may tuberculosis of the bones

be treated by hydrotherapy associated with heliotherapy, but this method promises good results in laryngeal tuberculosis, the prognosis of which ought to be amended as soon as our knowledge becomes a little more definite.³

Finally, even to patients with pulmonary tuberculosis we should not refuse the help which in certain cases may be given them by means of hydro-mineral treatment applied with precaution. Sulphurous waters, whether taken internally or externally, have given appreciable results, and we may recall the results obtained by our forbears from a cure at

Eaux-Bonnes. It is only the indiscriminate recommendation of badly selected patients that has caused this treatment to fall into discredit. Is this a reason for denying the services the springs have rendered? We are taking up this matter again, and it would seem that the sclerosal forms of tuberculosis where the pleura are predominantly affected can be treated advantageously by our Escaldes waters, after a few weeks' climatic treatment.

To sum up, setting aside all treatment by drugs, among which the doctor, nevertheless, will often find helpful tools, I am of the opinion that at the present time all pulmonary tuberculosis cases where suppuration occurs as revealed by the ear or the screen—or even where the disease is in rapid evolution—should have recourse to Forlanini. Pulmonary compression will work wonders, provided that it be properly carried out. To achieve this purpose, and in order to make up for any possible insufficiency of compression, I inaugurated in France as early as 1913, contemporaneously with Jacobæus in Sweden, the method of dividing pleural bands.⁴ I have since published a number of results confirmed by radiograms. The accompanying radiograms show a lung prevented from total collapse by a filiform adhesion and the result of division of this adhesion.

But besides such surgical measures, the simple and fundamental methods of treatment must never be overlooked—namely, rest, open air, and sunshine.

⁴ Liberation by Cautey of Pleural Adhesions during Treatment by Pneumothorax (Presse Médicale, No. 41, May 24th, 1922).

Radiograms showing a lung prevented from total collapse by a filiform adhesion and the result of division of this adhesion.

suppression of the cough and expectoration—are obtained in a few weeks by progressively conducted heliotherapeutics under Rollier's system. The disappearance of fever under the influence of the sun cure is anything but exceptional, and I have many times witnessed, after a few sun treatments, a drop in temperature which other treatments had been powerless to bring about. Auscultation shows drying-up of the suppuration centres, and even the radiological control, after a few months' treatment, will confirm progress due to the action of the sun, and further, it is very satisfactory to note how heliotherapeutic treatment, by inducing better nutrition, restores to our patients the symmetry and contour of their bodies.

But prudence is necessary. Not everyone can go to the mountains or take the sun cure. All congestive and evolutive patients should be kept in the plains, at least for the time necessary to reduce their temperature; for the same reason it would be more judicious and less risky for pneumothorax treatment to commence in the plains. As soon as the symptoms of tuberculous activity appear to slacken, all pulmonary cases, whether with or without pneumothorax, and especially those where the pleura is chiefly affected, may be taken to higher ground in order to benefit by the heliotherapeutic cure all the year round.

Since 1913 I have treated all my pneumothorax cases in this manner, and, thanks to this method, I have been able to obtain remarkable and definite results with patients who, owing to the bilateral condition of their lesions, seemed to be excluded from any hope of cure. Further, and as a corollary to hygienic treatment, I would add the sulphur water

Clinical and Laboratory Notes.

A CASE OF AIR-EMBOLISM OCCURRING DURING URETHROSCOPY.

BY RICHARD S. ROPER, F.R.C.S. EDIN.,
CLINICAL ASSISTANT, UROLOGICAL DEPARTMENT,
KING'S COLLEGE HOSPITAL.

THE possibility of the rare accident described in the following case and its gravity warrant the facts being placed upon record:—

W. A., aged 60, was sent to the Urological Department, King's College Hospital, on Jan. 2nd, 1924, complaining of difficulty in micturition, which had been relieved by passage per urethram of a small solid substance. The patient brought with him in a test-tube some clear urine with a piece of tissue in it which on section subsequently was found to be blood-clot.

Examination of the abdomen revealed nothing abnormal. Clear urine which contained a few shreds was passed easily, though in small stream. I passed a No. 10 coudé catheter, which was held up in the region of the bulb, and although the instrument was used with care, slight bleeding started at once. The urethroscope tube was then passed and the urethra thoroughly dried. A Joly instrument was used and under air inflation a good view was obtained. The walls of the urethra in front of the bulb appeared covered with granulation tissue which no doubt was responsible for the ease with which bleeding occurred. It was also possible that the condition might be epitheliomatous. No actual stricture could be seen beyond the granulation tissue.

As I was removing the urethroscope I noticed some surgical emphysema of the penis, and at once realised that as air had entered the tissues there was a danger of air-embolism. From the appearance of the patient it was apparent that this had already taken place. From the time air was first pumped into the urethra to the time symptoms first occurred about three minutes elapsed. The patient was dazed and restless and constantly moved his head from side to side. He was gradually losing consciousness. He became cyanosed, and the breathing began to be stertorous. The respiration slowed and became sighing in character and eventually ceased. The pulse continued to beat feebly after cessation of respiration, and later could no longer be felt at the wrist. The corneal reflex was never lost. About eight minutes elapsed between the time the symptoms first occurred and the failure of both respiration and circulation. In the meantime injections of strychnine and camphor were given and oxygen sprayed over the face. When respiration ceased artificial respiration was resorted to, but was only maintained a few minutes before the patient began to move his limbs, and normal respiration was restored.

After passing through a stage of great restlessness during which his desire seemed to be to sit up he gradually regained consciousness. It was noticed that during the repeated attempts to sit up the extra exertion called for caused the pulse to become imperceptible at the wrist. He was at once admitted to hospital, recovered completely in a few hours, and was discharged in a few days. A few weeks later this patient was admitted to the hospital under the care of Sir John Thomson-Walker, who excised a simple stricture and performed end-to-end suture of the urethra. I passed a No. 16 bougie two months later with ease.

Discussion.

On looking through the literature of air-embolism following surgical interference for the last 20 years, I find that most cases seem to have occurred in connexion with operations on the lungs and air-passages. A few cases have taken place after injection of the uterus with air or fluids in procuring abortion.¹ No reference in connexion with urology is found until 1913, when three cases were reported after distension of the bladder with air before prostatectomy. All three cases were fatal.^{2 3 4} The only case reported of air-embolism during urethroscopy was that by Mr. Ogier Ward in 1923, which was also fatal.⁵ Mr. Swift Joly tells me that some years ago two cases of sudden death took place during urethroscopy at St. Peter's Hospital which were at the time thought to be due to urethral shock, but that these cases were most likely due to air-embolism. Air-embolism in connexion with urethroscopy is therefore a real

danger and should always be borne in mind, especially in cases where the urethroscope tube fits tightly or when there has been hæmorrhage from the urethra. It is, of course, advisable not to use the urethroscope within 14 days of instrumentation for dilatation of stricture or where hæmorrhage has taken place from the urethra after surgical interference. Even if there has been no instrumentation at all it is quite impossible to be sure that there may not be a small abrasion of the urethral mucous membrane through which air can be forced into the vessels. At the same time, rare accidents of this kind should not deter one from using a valuable instrument with due precaution.

I am indebted to Mr. J. Everidge for permission to publish this case.

AN UNUSUAL CASE OF DISPLACEMENT OF ONE EYEBALL DUE TO A MYXOMA OF THE FRONTAL SINUS.

BY GEORGES KLIONSKY, M.B., B.S. LOND.,
HOUSE SURGEON, LONDON JEWISH HOSPITAL.

DISPLACEMENT of the eyeball due to disease of the frontal sinus is sufficiently uncommon in itself, but when accompanied by the unusual features of the case to be described it becomes worthy of record.

A married woman, aged 60, was admitted to the London Jewish Hospital on Oct. 9th, 1924, complaining of diplopia. The diplopia had been noticed for the last three months, but had occurred on one or two occasions during the preceding six months. There were no other symptoms in the history. The actual displacement of the eyeball was only noticed by the patient's relatives for about two weeks before admission. There was no pain in the eye, no headaches or vomiting, no nasal discharge. The right eye had been swollen three months before (? condition), but this had subsided in a few days under treatment with hot fomentations. There was a history of acute pain in both eyes 15 years ago. Operation was advised and not performed; the condition probably was some form of glaucoma. For the last three or four years the patient had been under treatment for rheumatoid arthritis.

Examination showed the left eye to be normal in every respect. The right eye was displaced forwards, downwards, and outwards, and the movements were limited upwards and inwards. There was no conjunctival injection. The fundus was quite normal. There was no pulsation of the eye, and no deformity or tenderness in the region of the orbit could be made out. Nasal examination revealed no discharge and no apparent abnormality except a slightly deflected septum. The X ray report was "Nothing very definite to account for the condition." The sinuses and antra were clear. The patient showed no pyrexia during her stay at the hospital. The Wassermann reaction of the blood was negative. The general examination revealed no primary focus of any growth.

While the case was being investigated the patient had an attack of acute glaucoma in each eye. This subsided quickly under treatment with eserine.

The provisional diagnosis one was forced to make was that there was present on the upper inner wall of the orbit a new growth of some kind, and it was decided to explore the orbit and deal with the condition found.

Operation.—An incision was made through the upper eyelid. Exploration with the tip of the finger showed a large fairly soft swelling. Nothing further could be determined as to its nature, as it was too far back; and it was not possible to deal with it through the incision made. The eyeball was therefore enucleated and the outer canthus divided. The swelling was found to be semi-fluctuant, occupying nearly half the orbit and apparently extending forwards from the apex on the roof and outer wall of the orbit. It was decided to eviscerate the orbital contents, and with this in view a beginning was made to separate the periosteum from the roof of the orbit. A considerable quantity of thin, jelly-like mucus suddenly exuded from the swelling, and the raspatory used was found to lie in a large cavity with smooth walls. This was explored and found to consist of the frontal sinus extending above the orbit back-

wards and round to the external angle. There was no floor to it, and the swelling had apparently extended through the opening and had separated the periosteum from the bone. No opening into the infundibulum could be found. The whole of the contents of the cyst was evacuated, the lid sutured in place, and a small drainage-tube inserted.

Discussion.

True myxomata are rare tumours, and connective-tissue tumours and inflammatory swellings undergoing myxomatous degeneration look very much like them macroscopically. It is unfortunate that a microscopic slide of the material could not be obtained; but a diagnosis of myxoma is favoured in preference to that of mucocele, because of the absence of inflammatory changes in the sinus and the perfect smoothness of the walls. In the case of a mucocele, thickening of the lining membrane of the sinus might have been expected at least. The absence of an opening of the sinus into the nose doubtlessly led to the increased pressure which gradually caused erosion of the bone of the floor. The former would, of course, also account for absence of nasal symptoms, even assuming that the condition was inflammatory. It might also be pertinent to ask whether a myxoma would be more likely to cause erosion of bone in contact with it than a mucocele.

I should like to express my indebtedness to Mr. A. H. Levy for permitting the publication of these notes.

A USEFUL STAIN FOR BLOOD FILMS.

By A. KNYVETT GORDON, M.B., B.CH. CAMB.

IN the early literature of hæmatology difficulty often arises from the fact that different workers did not always use the same stain, and it is, therefore, not always easy to understand to what type of cell they were referring.

A considerable advance was made by the use of Jenner's, followed by Giemsa's stain, or, as it is commonly called, the panoptic method. This can be standardised, and is, in fact, now used by most hæmatologists. It has the advantage that the various granules characteristic of different types of cell are well brought out, which has not hitherto been possible by any other method. In the diagnosis of pernicious anæmia, for instance, the panoptic method is essential. It unfortunately necessitates the consecutive use of two stains, and if the materials of which either is composed are not accurately prepared, the stain goes wrong. The process also is somewhat lengthy and the technique not always easy. As a result of many experiments I have now found a single process stain which gives results indistinguishable from the panoptic method, and in a much shorter space of time.

The stain is based on Leishman's method, but consists of:—

Eosin-methylene-blue	0.02 g.
Eosin-methylene-violet	0.02 g.
Methyl-alcohol (pure for analysis) ..	25 c.cm.

The film is flooded with the undiluted stain for one minute. An equal part, approximately, of distilled water is then added on the slide and the diluted stain allowed to act for three minutes, followed by distilled water for approximately two minutes. The film is dried and mounted either in neutral Canada balsam, or, preferably, in green euparal, the use of which is conducive to permanence of the specimens and also improves the definition of the granules.

An additional advantage of this method is that a somewhat wide latitude is permissible both in time and dilutions.

The stain is prepared by Messrs. British Drug Houses, Ltd., to whose analyst, Mr. Tusting Cocking, F.I.C., I am indebted for the painstaking way in which he has carried out the experimental work on the technical side.

London, W.C.

ROYAL SOCIETY OF MEDICINE.

SECTION OF OPHTHALMOLOGY.

A MEETING of this section took place on Jan. 9th. Sir ARNOLD LAWSON, the President, occupying the chair.

Susceptibility of Nocturnal Animals to Ultra-Violet Light.

Prof. SIDNEY RUSS and the PRESIDENT communicated to the section results of their observations on this subject. These investigations, said Prof. Russ, were prompted by the question put during the war as to whether the night vision of naval officers and other ratings could be improved, as it was necessary that their vision in the poor light in which they worked should be as acute as possible. For the purpose of ascertaining whether this vision could be artificially assisted, it was suggested that by giving to the eye a certain fractional dose of light its sensitiveness to very dim lights might be increased. The result of the experimentation which was carried out was that if to a comparatively rested eye a small dose of light of the blue and violet region of the spectrum were applied, the eye became somewhat more sensitive in its perception of distant and dimly-lighted objects. By this means the acuity of vision could be increased about 15 per cent., a figure which was practically arrived at by others working independently. The compass charts of the first Zeppelin brought down in this country were found to be illuminated with this variety of light. The further question arose as to how transparent the eye was to light from different regions of the spectrum. In fresh specimens of human eyes available for the purpose, a small window was cut at the back of the retina and a quartz plate cemented on to that; thus for all practical purposes the eye was still there, but radiation could be transmitted through it and analysed, in order to see to what extent radiations were absorbed by the cornea, the humours of the eye, and the lens. The first experiment with the human eye showed that this organ was very absorbent of anything beyond a wave-length of about 3800. The question which arose in his mind was as to whether acuity of vision in a dim light depended upon the transparency of the eye for radiation beyond that wave-length, that is, of shorter wave-length. If so, it should show itself by a study of the same process in nocturnal animals. On eyes of animals obtained from the "Zoo" the same process was gone through, and, as depicted by spectra shown on the screen, there was found to be an extraordinary difference in the degree to which these violet and ultra-violet radiations were transmitted by the whole optical apparatus. Nocturnal animals were found to have, in general, a very marked transparency to radiation which did not seem to be transmitted through the human eye at all. There was a considerable absorption of radiations within the range of normal vision. It might not be so much a matter of the action of the retina as of that of other components of the eye. Nocturnal animals were understood to be those which hunted their prey by night, but in the case of some, such as the tiger, this hunt was partly a matter of scent. The range of radiations transmitted by the tiger's eye, though considerable, was not so great as in the eye of the night owl. Such a range of radiation entering the eye must, Prof. Russ thought, contribute very considerably to vision in a poor light, especially as shorter wave-lengths gave sharper images than did longer wave-lengths.

The PRESIDENT said the actual work in this investigation was done by Prof. Russ, and he (Sir Arnold Lawson) was little more than an interested onlooker. The experiments seemed to throw some

light on the power of nocturnal animals to achieve their purpose in light which would be quite inadequate for diurnal creatures. He considered that there were three possibilities: (1) Extra susceptibility to ultra-violet radiation might increase the consciousness of light in nocturnal animals, so that they could hunt successfully in a light which would be impossible for ourselves; (2) or there might be a greater power of image-formation, the longer visible spectrum giving a keener image; (3) the effect might be in both these directions. He did not know of any differences in the anatomy and physiology of eyes of nocturnal animals to account for their strange power, and Prof. Russ's experiments seemed to him the best basis for further research yet offered on the subject. They suggested a possible explanation of why people with apparently similar emmetropic refraction differed so widely in their power of image-formation. Some people were conscious of much shorter wave-length radiations than were others; was it therefore possible that in the eyes of people with extra keenness of vision there was an extra susceptibility to ultra-violet radiation? Could the gradations in keenness of vision be explained in this way? The problem of night-blindness was also illumined by this research, for people so afflicted might have a lack of ultra-violet appreciation.

Sir JOHN PARSONS asked whether the powers of different parts of the eyes examined were tested. Experiments done on rabbits' eyes by himself, and, later, by Fowler and by E. K. Martin, gave results which did not tally with those done by Prof. Russ, at least in regard to the human eye. One of the great difficulties in finding the absorption to various wave-lengths by the cornea, or by the lens, was that caused by the refractive effect of the tissues themselves. It was very difficult experimentally to make a window in a fresh eye such as was employed by Prof. Russ, and still get a very satisfactory exposure and a good absorption spectrum by that means. Much of the radiation was absorbed by the lens, and much was altered by the production by the lens of fluorescence. The experiment of sensitising the eye by dosing it with light of short wave-lengths was of such value as to demand extension, and he spoke of a very fine piece of work which had recently been done on the subject by Prof. Frank Allen of Winnipeg, who found that stimulation with rays from one end of the spectrum increased sensitivity to sensations derived from stimulation of the eye by other parts of the spectrum. He (Sir John Parsons) did not feel certain that if short wave-length radiations got into the eye they would increase its sensitivity and the acuity of vision. The eye possessed chromatic aberration, and the long and short wave-lengths could not both be accurately focused; usually the focusing was for some intermediate wave-length, which Hartridge found to be the yellow region of the spectrum. Monochromatic illumination was a different matter.

Prof. F. G. HOBDAY said that during the war Australian horses were used in Palestine for night-work because they did not suffer from night-blindness. He thought Prof. Russ's research could be usefully extended on eyes of recently-killed horses in the wild state, as they existed, for instance, on the Pampas.

Reply.

Prof. Russ, in reply, said he omitted to mention that the eyes used were subsequently examined as to the absorptive power of their separate portions. It was found that the lens was the most absorbent, next came the cornea, there being but little difference between the other two humours. With regard to the marked absorption by the lens, an explanation and demonstration of this absorption was furnished by a very marked fluorescence of the lens. Fluorescence argued absorption. He elaborated the point in some detail. The striking difference in the capacity of various animals adequately to function in dim lights was difficult to conceive of except by a great range

in transparency; it must be largely a question, ultimately, of how much energy was getting into the eye.

Mr. F. A. WILLIAMSON-NOBLE read an elaborate contribution, illustrated by means of the epidiascope, on

Inflammatory Pseudo-Tumours of the Orbit.

He dealt with three cases and explained that the term set out in the title had a clinical rather than a pathological significance; it caused proptosis, limitation of movement, increase in bulk of orbital tissues, and perhaps swelling of the lids. There was a slow onset, and none of the usual signs of inflammation. Macroscopically, the orbital contents, if removed, might strongly suggest tumour. Benedict and Knight were inclined to attribute these pseudo-tumours to focal infection elsewhere, which had been overlooked in the absence of symptoms and leucocytosis. But the evidence must be carefully sifted, and this should not be made a sort of scrap-heap for otherwise undiagnosable conditions. Birch-Hirschfeld made three useful groups of this condition. In the first he placed cases in which the recovery was spontaneous, or took place after the use of iodide of potassium, mercury, or quinine. In the second group an operation was performed without finding any tumour. The third group embraced the cases in which the macroscopical appearance of the orbital contents suggested tumour, but the microscope revealed a chronic inflammatory mass.

The first case related might be taken as a good example of the condition. It was that of a man, aged 25, who in July last attended hospital with marked proptosis of the right eye and much conjunctival injection. Movements were full and normal. Rhinological examination was negative. He was treated with mercury and iodide at once, without awaiting a Wassermann test. Three weeks later there was some limitation of movement in the right eye, and the proptosis was more marked. With glasses, vision in both eyes was 6/12. A month later he was taken into hospital, and mercury injections and potassium iodide were continued for a further fortnight, but without reducing the proptosis. Exploration revealed a hard mass of tissue in the orbit and no pus. Exenteration was performed a week or two later. He showed a photograph of the macroscopic appearance; there was a large white mass within the cone of muscles, moulded closely over the posterior surface of the sclerotic and quite surrounding the optic nerve. The nerve itself did not seem to be affected. The vessels showed great thickening, both the intima and the adventitia; in some instances this caused obliteration of the vessels. This was, no doubt, a gumma. In a similar case reported by Hine the Wassermann was negative, and, concerning the value of the Wassermann test, Harrison stated that it was frequent to obtain a negative reaction in cases of syphilis when only a small syphilitic lesion was present, and that help in doubtful cases was sometimes derived from a provocative injection of salvarsan or a derivative. Mr. Williamson-Noble's second case was that of a man, aged about 50, who, following influenza, developed what appeared to be a lymphoma. The condition seemed to have been predisposed to by the lowered resistance due to the influenzal attack. The remaining case of the condition was one in which a mass of young connective tissue formed as a result of irritation induced by the presence of cholesterol crystals. This was inflammatory only in the sense that it represented the reaction of tissue to injury.

The pre-operative diagnosis and treatment of the condition were very difficult. The presence of a lymphocytosis could not always be relied upon, as in two cases reported this was absent. The diagnosis involved a consideration of all the possible causes of proptosis, and he suggested that there should be an examination of the urine, especially for sugar; also a Wassermann test, and if this proved negative, repeated after a provocative dose of salvarsan.

Complement-fixation in regard to tubercle should be done, and a differential blood count, with a blood coagulation time. And there should certainly be a search for focal infections, with radiography of teeth and sinuses. Always the possibility of early Graves's disease must be considered, and an exploration should precede a decision to extirpate the orbital contents.

Mr. LINDSAY REA related a case of similar kind which had been under his care recently. The patient was a young man who was brought to hospital with his left eye proptosed, and the conjunctiva swollen and chemosed, so that the lids did not meet over the cornea. He denied venereal disease. Exploratory puncture with division of the external rectus revealed nothing. Subsequently the Wassermann was found positive. Vision in the eye concerned was reduced to bare perception of light. Three weeks later the other eye began to be proptosed. The man was put upon treatment by novarsenobillon, combined with iodide of potassium and mercury inunction. At the end of the third week the improvement was definite, and in the sixth week the eyes settled down, the lids again met, and vision was 6/6 in each eye. Even if the Wassermann had been negative, he would have persevered with antisymphilitic treatment.

Bi-temporal Hemianopia due to Fracture of Skull.

Mr. EGERTON GRAY showed a man who, in 1911, fell 12 feet and sustained a depressed fracture in the frontal region of the skull. There was severe epistaxis, and on recovering consciousness he complained of defective sight. There had been severe headache, and in certain positions there was double vision. He also lost the sense of smell. Pupils were equal and active, and there were no colour scotomata. There had been no albuminuria or polyuria, and his sugar tolerance was not increased. He had, however, peculiar nystagmoid movements of the head.—Mr. J. H. FISHER regarded the case as a very unusual one. The fracture must, in order to cause the symptoms, have run across the roof of the orbit and involved the cribriform plate and olfactory lobes, as well as implicating the optic chiasma.

Congenital Blindness without Obvious Ocular or Central Cause.

Mr. RAYNER BATTEN showed a sister (aged 6) and brother (aged 3) who were born blind, without obvious cause. The children were otherwise healthy and well formed. There were no evidences of congenital syphilis nor of central nervous disease. Wassermann was negative in both the children and their mother. The boy had about +6 of astigmatism, and the girl had hypermetropia in one eye, and hypermetropic astigmatism in the other. Whether the pupils reacted to light was doubtful. Both had slow nystagmus.—Mr. LESLIE PATON referred to two children in the same category whom he had had under observation for a number of years. These at first had head-nodding and nystagmus. They showed fine macular changes.—Mr. FISHER thought that in Mr. Batten's cases there were pathological changes in the retina and optic nerves. The boy had pallor of the disc, and the girl had thread-like retinal vessels, and in the lower part of her fundus was a definite sheathing with pigment of some of the vessels.—Mr. M. S. MAYOU spoke of a girl, aged 18, who was born blind and whose discs looked very similar to those of Mr. Batten's two cases. Two years after he saw her she died as the result of an accident, and the post-mortem showed she had large cysts occupying the occipital lobes, the cysts comprising a distension of the posterior horns of the lateral ventricles.—Dr. FRANCHESCHETTI (Zurich) thought it probable that these two children had a familial disease, and that it was likely the blindness might be due to colour-blindness. In the latter there was also a fine nystagmus.

Mr. P. G. DOYNE showed a patient with microphthalmia, a retinal cyst, and pedunculated growths along the line of the orbito-nasal fold.

NORTH OF ENGLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.

A MEETING of this Society was held at Manchester on Dec. 19th, 1924, Prof. A. DONALD, the President, in the chair, when Dr. KENNETH V. BAILEY read a paper on the

Pathology of Ectopic Müllerianoma (Pelvic Adenomyoma).

Dr. Bailey said that since the work of von Recklinghausen and Cullen towards the end of the nineteenth century—who first aroused full interest in the subject of "adenomyomatous" growths affecting the female pelvic organs—many authors had written on tumours of this class. In recent times, however, the condition had become associated pathologically with the name of Sampson, of Albany, U.S.A., and clinically with that of Donald, of Manchester. Hitherto, no attempt had been made to classify this tumour from a pathological and aetiological standpoint; its aetiology still remained in doubt and its life-history was, as yet, very imperfectly explained. However many instances of tumour formation there might be in the pelvis at the one time, they were all, aetiological, part of the one pathological condition, and must, therefore, be looked upon as part of the one tumour. They were, in fact, all brought about by the periodic or occasional invasion of the various pelvic organs or peritoneal surfaces by either endometrial tissue or Fallopian tubal epithelium.

Dr. Bailey classified the various tumour formations, which together constituted this pathological condition of the pelvis, into two types: (a) endometrial type; (b) Fallopian tube type. These two types differed essentially in their gross pathology and even more definitely in their histological characteristics. Both types, however, might create widespread lesions throughout the pelvis. It was the ovary, however, which exhibited the results of the growth and activity of these tissues to the fullest extent. A relatively insignificant reaction might be the only evidence of this growth in the uterine wall when, in the same case, the ovary had been transformed into a distended sac containing dark, tarry blood, a product of the activity of the invading tissue. It was from the ovary, therefore, that the life-history of this condition could best be studied.

Dr. Bailey said that the chief differences in the gross pathology between the endometrial and Fallopian tube types of this condition were as follows:—

Endometrial Type.—(1) An affected ovary may exhibit any stage from that of possessing small, diffuse hæmorrhagic areas on its surface to advanced excavation and distension transforming it into a distended sac filled with chocolate-coloured fluid blood, and cellular debris. (2) The lesions produced in the ovaries, uterine wall, pelvic ligament, rectum, &c., are obviously of an active local invasive nature. The impression of great activity on the part of the abnormally placed tissue is produced. Excavation may be extensive. (3) The pelvic adhesions are of a very dense character. The ovaries are fastened to the uterine wall or broad ligament by actual new growth in many instances and are often very difficult to detach.

Fallopian Tube Type.—(1) Is evidenced by small scattered hæmorrhages on the ovarian surface, of varying colour from bright red to almost black according to their age; advanced conditions exhibit erosion of the ovarian surface. A small depressed scar may mark the site of an old deposit. (2) This type is characterised by the relatively light nature of the pelvic adhesions, differing markedly from the dense character of those produced by the endometrial type. (3) Blood cavities in the ovary are not produced. (4) Both macroscopically and microscopically there is the appearance of only slight invasiveness on the part of the misplaced tissue, which only penetrates at most to a depth of about 2 mm. below the surface of the organ in which it is growing.

The chief microscopical differences between these two types, Dr. Bailey said, would be evident in a brief description of their life-history.

*Life-history of the Endometrial Type.**(a) As it Affected the Ovary.*

Stage 1.—Not visible to the naked eye. It was seen microscopically to be of the nature of a deposit of typical endometrial tissue on the ovarian surface. Perhaps one or two typical gland spaces situated in fine fibrin network which also contained endometrial stroma cells might be situated on the surface of the ovary or perhaps scattered columnar cells identical with those which line the glands of the endometrium might form this primary deposit.

Stage 2.—Invasion of the ovarian stroma by this abnormally placed endometrium. (a) If the primary endometrial deposit occupied a relatively wide area on the ovarian surface, this stage was visible to the naked eye as a minute hæmorrhagic excavation thereon and microscopically the invading endometrium could be seen to have commenced its penetration of the ovarian cortex. (b) If the primary site were relatively small in area, this stage was marked by the production of a small, somewhat diffuse hæmorrhagic bleb on the surface of the ovary. Microscopically, a pseudo-cyst was formed immediately beneath the ovarian surface (but connected with it) containing the active endometrium and extravasated blood.

Stage 3.—(a) Misplaced endometrium invading over a relatively wide area penetrated the ovarian stroma in a wedge-shaped formation. The actual glandular elements were preceded by masses of stroma cells. This was the stage of intense activity on the part of the invading tissue, both in penetration and proliferation. (b) Endometrium actively invading from a relatively small surface area might do so by a long, apparently quickly formed channel, at the termination of which the most advanced endometrium was situated in one or more actively proliferating clumps.

Stage 4.—Commencing degeneration of the invading elements. At this stage the height of activity of the misplaced tissue was reached or passed. It was visible to the naked eye as a "seam" of chocolate fluid blood which stretched for varying distances into the tissues of the ovary and marked the track of invasion of the penetrating endometrium. The chocolate fluid blood was the long-retained product of the menstrual activity of the endometrium and was composed of blood corpuscles, blood pigment, degenerated epithelial cells, phagocytes, and cellular debris. Microscopically, the invading endometrium was always found in connexion with the deepest part of the "chocolate seam" and was seen to be undergoing degenerative change.

Stage 5.—Commencing cavity formation in the ovary itself. Further extravasations of menstrual blood by endometrium situated in connexion with a "chocolate seam" caused local distension of the seam by liquefaction of the surrounding ovarian stroma and an actual cavity was formed in the substance of the ovary. Microscopically, endometrial tissue of vitality perhaps equal to that found in association with Stage 4 was seen situated in close connexion with this cavity.

Stage 6.—Last stage. Here the ovary was transformed into a distended "sac" the size of a tangerine orange or even larger. The walls of this "sac" were composed of the thinned-out and compressed ovarian stroma itself, deeply and irregularly infiltrated by old blood. The extensively excavated ovary was filled with chocolate fluid blood, the product of the activity of the invading elements. Such an ovary was always densely adherent at the primary site of invasion to neighbouring structures—e.g., uterine body or the base of the broad ligament. Microscopically, the remains of degenerated endometrial tissue might possibly be found in the deepest parts of the large cavity.

The stages in the life-history of the endometrial type of this growth were thus brought about by a process of pure invasion of the affected organ—e.g., ovary—by the misplaced endometrium. Excavation was commenced with consequent cavity formation. The terms "chocolate cyst," "hæmorrhagic cyst" used by other authors were erroneous. A "blood cavity" was produced in the ovary by this process of excavation. There was no cyst wall produced by the activity of the foreign elements. Dr. Bailey believed that the ovary became adherent to neighbouring structures during Stage 2, when slight hæmorrhagic erosion or excavation had taken place on its surface. It might escape adhesion for a time in this stage when a small space was formed immediately beneath the surface, but would sooner or later become adherent as the area of primary deposit of the endometrial tissue became larger. The ovary was, therefore, adherent at a very early stage in the life-history

of the tumour and remained so during the growth of it. There was no "perforation" of the "cyst" as described by Sampson and others. The mouth of the blood cavity was formed at the commencement of the growth inwards of the endometrial tissue, and the site of "perforation" mentioned in literature was the cavity mouth which was always found glued to some neighbouring structure. Dr. Bailey was of the opinion that the tissue found in these blood cavities and excavations was endometrium because (1) it was morphologically identical; (2) its function was the same—viz, menstruation—and this occurred concurrently with menstruation in the uterine endometrium; and (3) aetiologically, as he hoped to prove, the glandular and stromal elements were derived from the uterine cavity itself.

(b) Endometrial Invasion of the Uterine Body from Without.

Stage 1.—Implantation on the uterine surface of a clump of endometrial glands or epithelium and stroma cells. This, if extensive enough, might be visible to the naked eye as a minute hæmorrhagic spot or bleb of a somewhat diffuse nature.

Stage 2.—Active penetration and proliferation on the part of the invading endometrium. The actual glandular elements were preceded by masses of typical stroma cells which pushed their way in between the muscle bundles of the uterine body. Menstrual blood was extravasated into this "stromal bed" which in areas of intense extravasation became transformed into a highly hæmorrhagic, loose, spindle-celled matrix.

Stage 3.—Characterised by microscopical evidence of retrogressive change in the misplaced endometrium. The glands had become widely dilated and lined by cuboidal or low epithelium. They were either empty or contained old blood and were surrounded by a thin bed of stroma cells which did not exhibit any invasive activity.

(c) Endometrial Invasion as it Affects the Fallopian Tube from Without.

Dr. Bailey had seen only one case in which the Fallopian tube was definitely invaded by endometrial tissue deposited on its serous surface from without. In this the fimbrial end of the tube exhibited two small, discrete chocolate-coloured areas on its surface and another diffuse hæmorrhagic area at some little distance from these. Microscopically, the muscular wall of the tube could be seen to be invaded by typical endometrial elements having no connexion whatever with the epithelial elements of the tubal lumen. This, he held, was the only case of the kind as yet reported.

Life-history of the Fallopian Tube Type.

Stage 1.—Like the endometrial type, this stage was not visible to the naked eye. It consisted of a deposition on the ovarian surface of a mass or strip of loose Fallopian epithelial cells, of the same morphological characteristics as those which lined the tubal plicæ. These cells were of a high cylindric variety. Their sides were concave, the middle of the cell body appearing constricted. Their surfaces were relatively broad and were ciliated. Their nuclei were situated nearer the surface than the base. These cells were packed closely together in a somewhat disorderly manner when observed in rows, and a constant feature was that their surfaces presented a "dirty" appearance due to adherent particles of blood debris (fibrin) which had apparently been attracted by, and become entangled in, the cilia attached to them.

Stage 2.—Commencing invasion of the ovarian stroma of these cells. This took the form of a minute indentation in the ovarian surface lined by the invading cells and a very slight rarefaction of the subjacent tissue. There was no evidence of a "stromal bed" as in the endometrial type. This stage, also, was not visible to the naked eye.

Stage 3.—From this point penetration of the ovarian stroma continued until a stage was reached at which one or more definite gland-like spaces were formed at short distances below the ovarian surface. Often only one space was formed, rarely more than three or four together. These spaces were widely dilated, atypical in shape, as compared with endometrial gland spaces, and lined by the high columnar ciliated cell of this type. They always rested directly on the ovarian stroma. They had no "bed" of stroma cells. There was only a relatively slight rarefaction of the surrounding ovarian tissue, brought about in many of the cases by the effect of extravasated blood in the vicinity.

Stage 4.—From this point onwards the abnormally placed Fallopian elements began to degenerate. Very little further penetration took place. The affected ovary was never deeply invaded. There was no excavation. With degeneration of the epithelial cells lining these gland-like spaces and extravasation of the contained blood into the surrounding ovarian stroma, the life-history of Fallopian epithelial invasion of the ovary came to an end. Stages 3 and 4 could be detected in the gross specimen by the presence on the surface of the ovary of minute, discrete, hæmorrhagic spots, varying in colour from bright red to black, according to their age. A depressed scar might mark the site of a very old deposit.

Dr. Bailey held that Fallopian tubal epithelium was unable to invade the musculature of the uterine body. He had found evidence of it, however, in the ovarian ligament and Fallopian tube wall.

Ætiology.

Dr. Bailey believed the primary deposit on the ovarian surface (or any other surface) to be brought about by the "shedding" on to it of endometrial or Fallopian tubal epithelium emanating from the uterine cavity or Fallopian tubal lumen respectively, as the result of a process of retrograde menstruation or back-flow through the tubes, by which elements of this nature were eventually expelled via the abdominal ostium of the Fallopian tube and deposited on the surfaces of the various pelvic organs.

To prove this assertion he had examined the uterine cavity and the lumen of the interstitial, isthmic, ampullary, and fimbrial portions of the Fallopian tube in undamaged specimens of pelvic organs affected by this tumour removed during menstruation. In these he could demonstrate the presence of free blood and epithelial elements, the only possible source of which could be from the uterine cavity itself. That Stage 1 in each type was of the nature of a deposit on the surface of the affected organ he believed on account of the fact that its microscopical appearance could in no way be accounted for by any of the numerous theories hitherto advanced in the search for the ætiology of this condition.

Nomenclature.

Many names had been ascribed to tumours of the female pelvic organs containing aberrant epithelial elements. Some were suggested on ætiological grounds—e.g., "salpingitis isthmica nodosa," "adenomyositis tubæ," and "adenomyo-salpingitis"; others on a pathological basis—e.g., "adenomyoma" as the condition is called to-day, "endometrioma," as Blair Bell named it, or "adenoma" as Sampson latterly called it. Dr. Bailey, however, considered that from its pathology and ætiology, as he had described it, this tumour which was in itself (1) locally malignant, (2) did not tend to the formation of metastases, and (3) originated in whatever organ it was growing "from without," was most comprehensively described as "ectopic Müllerianoma."

The discussion was adjourned.

Specimens and cases were presented and discussed by the PRESIDENT and by Drs. BLAIR BELL, FOTHERGILL, IVENS, FLETCHER SHAW, and DOUGAL.

NURSING HOME FOR MIDDLE CLASSES AT LIVERPOOL.

By the generosity of the late Mr. Robert Davies, shipowner, of Wallasey, and his executors, a committee of the Stanley Hospital, Liverpool, has been able to purchase and equip the beautiful mansion of "Kiln Hey," Sandford Park, West Derby, as a nursing home intended exclusively for the use of middle-class patients of limited means. A sum of £10,000 was presented to the committee and this with other generous donations has enabled the committee to make this pioneer effort to meet the needs of that large section of the public whose case is not served by the hospitals or private nursing home. The "Robert Davies" Nursing Home is managed by a committee distinct from that of the Stanley Hospital, but the chairman is common to both institutions. Thirty beds are available, but there is no resident medical staff, as each patient will be attended by his or her own surgeon or physician, who will conform to the rules of the home. Patients will be charged three guineas a week in addition to professional fees. Maternity patients will be received only by special permission, and no infectious or mental cases will be admitted.

Reviews and Notices of Books.

THE EVOLUTION OF MAN.

Essays by G. ELLIOT SMITH, M.A., M.D., Litt.D., F.R.C.P., F.R.S. London: Humphrey Milford. Oxford University Press. 1924. Pp. 158. 8s. 6d.

THE essential theme of this book, as the author says in his preface, is the development of the view of the importance of the cultivation of vision in the evolution of man's intellect. Such a theme calls for a general review of the course of human evolution, and this is provided in the three main chapters of the work—on the Evolution of Man, Primitive Man, and The Human Brain. A "foreword" on Man's Pedigree leads up to the first chapter. The subject-matters of the chapters are derived from various addresses given at different times before different audiences: they have been brought together to meet the wants of anthropological students who desire information on these more recent views. But for those also who are only amateurs in the science this book will be a fascinating study, for it is the work of an acknowledged master of the subject, dealing lucidly and learnedly with many of the wider problems contained within it. Moreover, there are no sterile references, nor collections of unrelated facts, to annoy and bore such an amateur anthropologist, while the serious student has an authoritative work to which he can refer with confidence. We confess that when we had finished reading this little book we turned back and read it through again, with increasing pleasure and profit. We had hoped at first to come across some discussion of such things as the anatomical details of the Rhodesian skull, or of the reasons for refusing descendant rank to the Neanderthal man with reference to the original owner of the Mauer jaw, or maybe some talk about the dentition of *Propliopithecus* and *Eoanthropus*, for Prof. Elliot Smith's remarks on these and many other such points would be of great interest and importance; but one recognises, of course, that such matters do not really come within the scheme of this book and would be out of place. The fundamental difference of outlook between the "historical" and "evolutionary" schools of ethnological thought are dealt with vigorously by Prof. Elliot Smith, who is a leading exponent of the former school, and does not spare his opponents in his trenchant and reasonable criticism.

The book is not only of great interest, but it is one that will give some idea of the present trend of anthropological thought to those who are not concerned as experts in the formation of it. It has some excellent illustrations and is well produced.

PRACTICAL SURGERY.

By VICTOR PAUCHET. Translated by F. R. B. ATKINSON, M.D., C.M. Edin. With a Preface by Sir CHARLES GORDON-WATSON, C.M.G., F.R.C.S. London: Ernest Benn, Ltd. 1924. Vols. I. and II. Illustrated. Pp. 252 and 293. 18s. 6d. per vol.

THIS is an original type of book in that it is an atlas of drawings made from actual operations, accompanied not simply by a description of procedure, but by remarks on the advisability of employing the different methods in the light of the author's own experience. This is a commendable feature, especially so as the advice tendered is essentially practical and obviously well considered. Of the two volumes, the second is the more valuable. In the first an indifferent and inadequate chapter on surgical technique is followed by descriptions of operations upon hernia, hydrocele, hæmorrhoids, and a few other matters which proceed upon generally accepted lines. An interesting method of operating upon vesico-vaginal fistula is described, by which free access to the site of operation is obtained. The results of it are said to be exceptionally good. The author adopts Sir Arbuthnot Lane's views as to the far-

reaching results of intestinal stasis and consequently recommends colectomy or partial colectomy for their relief. The chapter on gastro-jejunal ulceration gives good advice and shows very well how operations for its relief should be carried out.

In the second volume the author has been assisted in places by Thierry de Martel, J. L. Faure, and H. Ruberis-Duval. The remarks upon the use of radium in carcinoma uteri, carcinoma recti, and fibroids of the uterus are worth close study. Transperitoneal nephrectomy for large malignant tumours is performed through a transverse incision. Perineal prostatectomy is accorded its right place and a practical point in the technique of enucleation suprapubically in two stages is brought out. If there is much delay after the cystostomy the line of separation may have fibrosed up. Pauchet points out that when such difficulty is met, it is right to stop the attempt at removal of the prostate and to wait for some days, when a new line of separation will appear as the result of the inflammatory reaction. We read that the author has performed five complete gastrectomies and that one subject is in excellent health after some years. Gastro-enterostomy, according to Roux's method, is recommended for some purposes and the Murphy button still seems to be used.

There are one or two mistakes in translation, as on p. 3, Vol. II., where the first word on line 18 should obviously be "above" not "below," and on p. 111, Vol. II., where operating upon a prostate in two stages is stated to double the chances of infection. On p. 143, Vol. II., the translator tells us to pass a jejunal loop across an opening in the transverse mesocolon instead of through it, and on p. 140 of the same volume he refers to an "abandoned stitch." The pictures are excellent and show everything that it is essential to see.

NOTABLE BRITISH TRIALS.

Trial of Henry Fauntleroy. Edited by HORACE BLEACKLEY. London and Edinburgh: William Hodge and Company, Ltd. 1924. Pp. 269. 10s. 6d.

THE latest volume in the series of Notable British Trials tells the story of Henry Fauntleroy, to which there are added as appendices the brief biographies of 15 other forgers, who were convicted and hanged between the years 1750 and the accession of Queen Victoria, in the first year of whose reign capital punishment in cases of forgery was abolished.

There is no particular medical interest in the Fauntleroy case, and it is difficult now to realise why it should have created the vast excitement that it did. Fauntleroy, born in middle-class circles, was a man of good extraction and heredity; he was licentious, but the Regency was not strait-laced, and he had no mental aberration of any kind; his large forgeries—for a quarter of a million was a large sum 100 years ago—were committed in order to maintain the bank, of which he was managing partner, in such an apparent position of solidity that he could continue to draw an income which was wholly unjustifiable. No great passion of any sort seems to have influenced his life, and he was probably impelled to a capital crime by nothing more forcible than his vanity, which could not bear the public appearance of failure, or the surrender of a reputation as a *bon viveur*. Fauntleroy was hanged outside Newgate in the presence of the largest crowd which had ever assembled for the loathsome recreation of seeing a hanging, and the stringent precautions in guarding the body after execution led to the circulation of the rumour that the corpse had been resuscitated by a friendly surgeon. The same story had been told previously in connexion with many famous criminals from Jack Sheppard downwards, and in the case of Dr. Dodd, who was hanged for forgery some 40 years before Fauntleroy, such an attempt really was made. At any rate the popular story is that the hangman, whose duty it used to be to complete the dreadful work by pulling down the victim from the knees, arranged to support the body of Dodd from below while it was being taken down; mean-

time the driver of a hearse which was in readiness had been told to go with all speed to an address where a hot bath had been prepared and where the great John Hunter was waiting, or some other celebrated surgeon. It seems to be true that in the case of Dr. Dodd an unsuccessful attempt to resuscitate the hanged man was really made, though we know of no evidence to connect Hunter with the exploit, and indeed at the particular date he was a severe physical sufferer himself.

Mr. Bleackley has edited both the main story and the various appendices with care and skill, and we gather from the book, now here and now there, many vivid pictures of life at the close of the eighteenth and the beginning of the nineteenth centuries.

THE STRUCTURE OF PROTOPLASM.

La matière vivante, organisations et différenciations, origines de la vie, colloïdes et mitochondries. By J. KUNSTLER and F. PRÉVOST. Paris: Masson et Cie. 1924. With 82 figures. Pp. 252. Fr. 18.

SINCE men had microscopes it has been a regularly recurring dream that it was possible to get behind cells and find in the intimate structure of protoplasm some smaller units which should represent the ultimate basis of life. Béchamp had his microzymes, Altmann his bioblasts—which at any rate have the advantage of being easily and plainly stained so that they make pretty microscopic objects—there have been many micellæ and nowadays mitochondria are thought by some to be the same sort of thing. Prof. Kunstler believes that living matter (which he prefers to call "sarcodé" rather than "protoplasm" because the former word was used first and by a Frenchman) is composed of vesicular elements either joined together in stable and compact masses as cells or diffused in the body-fluids and capable of motion and an autonomous life. He is at some pains to point out that he advanced this view before Bütschli put forward his spongy interpretation of protoplasm, and his line of attack may be surmised from his giving in a footnote the curious bit of history that "this German professor during the invasion of 1870-71 had the good taste to date his papers from the various French towns he passed through." He differs from most recent authors in the same field by believing that chemical reactions cannot explain the phenomena of life, and that the curious behaviours of colloids and emulsions have no real analogy with vital activities; there is no continuity between live and dead. The illustrations are mostly bad micro-photographs and Prof. Kunstler's interpretation of them will not carry universal conviction.

UROLOGY.

Urologische Operationslehre. By Prof. Dr. FRITZ VOELCKER and Dr. ERICH WOSSIDLO. Leipzig: Georg Thieme. 1924. With 504 illustrations. Pp. 654. \$8.30.

THIS book on genito-urinary operations is comprehensive and is, moreover, generously supplied with illustrations. In it an account is given not only of the more usual surgical procedures known to the general surgeon, but also of those intravesical operations carried out through cystoscopes and urethroscopes that belong more to the province of the specialist. The ingenuity of the German school of urology in designing and manufacturing cystoscopes and urethroscopes is well known, and it is not surprising, therefore, that this portion of the work is so up to date and complete. In it are included descriptions and illustrations of several new instruments that have not yet appeared in English literature, for example, cystoscopes for the application of radium to the bladder growths and various new forms of operating forceps, scissors, and snares for use in operative cystoscopy. In the chapter on operations on the prostate it is, perhaps, surprising to find that so little attention has been given to per-urethral operations and especially to diathermy.

It is true that Bottini's operation is described, but surely this procedure belongs only to the past and might be allowed to drop out of text-books except as an historical reference.

These points are, however, of minor importance, and the book is probably the most important, comprehensive, and useful work that has appeared since the war on this particular subject in the German language. Both authors and publishers are to be congratulated on the result of their efforts.

PSYCHOLOGY AND THE SCIENCES.

Edited by WILLIAM BROWN, M.D., D.Sc., M.R.C.P. With contributions by J. S. HALDANE, R. R. MARETT, F. C. S. SCHILLER, L. P. JACKS, A. E. J. RAWLINSON, M. W. KEATINGE, WILLIAM BROWN, and T. W. MITCHELL. London: A. and C. Black, 1924. Pp. 184. 7s. 6d.

PSYCHOLOGY, as the author of the third essay in this book points out, seems to be a medley of discrepant and antagonistic schools. Yet its importance to such subjects as ethics, logic, education, and theology is indicated by these essays, which formed the material of eight lectures delivered at Oxford by active workers who speak with authority, each upon his own subject. Written in a scholarly manner, they are sometimes brilliant and always entertaining; never prejudiced in any bad sense of the word, they yet show the influence of his own specialty upon the individual writer. Prof. Haldane, for example, looks forward to the time when, with an adequate physiology of the nervous system, the "confused pseudo-psychology of the unconscious" will disappear—a point of view against which Dr. William Brown is moved to gentle remonstrance. Principal Jacks fears that psychology may undermine the ground on which ethical construction has to rest, whilst, on the other hand, Dr. Schiller hopes to extract from psychology abundant stimulus for a really competent and progressive science of logic. Dr. Keatinge, in contrasting Bain's "Mental and Moral Science" with McDougall's "Outlines of Psychology" brings out clearly the ineffectiveness of the older psychology in its bearing upon life and conduct. Dr. T. W. Mitchell, an ex-president of the Society for Psychical Research, discusses in the final chapter the theories of multiple personality and mediumistic "control," and inclines to the belief that the medium may acquire knowledge by some other channel than the ordinary media of the senses. The book is an interesting summary of the attitude of thoughtful men towards the newer developments of psychology.

BIOCHEMISTRY.

A Laboratory Course for Medical Students. By I. FROST, M.B., B.S. Lond., M.R.C.S. Eng., L.R.C.P. Lond., Biochemist, Medical College, Madras; formerly Assistant Lecturer in Physiology, University of Birmingham. Madras: Government Press. 1924. Pp. 56.

THIS little book covers a multitude of subjects in practical biochemistry. The first experiments are designed to demonstrate the properties of colloidal solutions, and to elucidate various points such as hydrogen-ion concentration. Then follow the usual tests for proteins, fats, carbohydrates, blood, milk, &c. This orthodox section, as one might term it, is very condensed, yet at the same time contains practically all the experiments described in larger books. By far the most interesting part to discuss is the unorthodox section. The author has boldly separated himself from the traditional "advanced" experiments, with rabbits' livers, meat, and bread, and has struck an entirely original note for a small elementary laboratory guide. In place of the usual depressing experiments, he has substituted methods of blood analysis, colorimetric determinate of hydrogen-ion concentration, the estimation of urinary diastase, &c.; methods of preparing buffer solutions, with a complete range of pH are given; the Van der Bergh

reaction is described. Coming upon these descriptions without warning in the middle of the book reacts upon the reader like a sudden breath of fresh air. In his 56 pages the author gives his students a much wider view of the subject than many of the so-called standard works.

The book is obviously meant as a summary, and in places savours very much of the "cram" book. On the whole, however, the author is to be congratulated for his courage in attempting to include some really practical methods, and in his attempt to stimulate the reader to interests outside egg-white, bread, and lard.

THE STORY OF EARLY CHEMISTRY.

By JOHN MAXSON STILLMAN, late Emeritus Professor of Chemistry, Stanford University. London and New York: D. Appleton and Co. 1924. Pp. 566. 18s.

IN writing this book it has been the author's endeavour "to tell the story of the development of chemical knowledge and science, from the earliest times to the close of the eighteenth century, in a connected and systematic way, not as a condensed encyclopædia." The fact that most of the earlier chemists were physicians makes such a book of interest to the student of the historical aspect of medicine, as well as to the student of chemical history; in this connexion we may remind those who are in favour of curtailing the time spent by medical students on chemistry, that so long ago as the sixteenth century Paracelsus was urging physicians of his time to recognise the importance of chemistry in the development of medicine. Some of the disabilities under which the earlier workers laboured are not unknown at the present day. We are told of Paracelsus (1526–41) that although he wrote voluminously, only a few of his more important medical and surgical works were published during his lifetime, since the opposition of the faculties more than once blocked his plans of publication. He often emphasised his conviction "of the necessity of experiment and experience of the physician as against looking for all knowledge to the traditional authorities." In contrast to this we read of Sylvius (1659–74) that his tendency was like that of nearly all the medical chemists of his period, "to accept a plausible analogy instead of waiting for more basis in facts for his conclusions."

The book is written attractively. We regret the death of the author, which occurred before the first proofs were received from the publishers.

OTO-RHINO-LARYNGOLOGY.

La biopsie clinique en oto-rhino-laryngologie. By Dr. ANDRÉ AUBIN, Assistant du Service d'Oto-rhino-laryngologie de l'Hôpital St. Louis. Paris: Vigot Frères. 1924. Pp. 334. Fr. 30.

BIOPSY is defined as "the operation which consists in excising from the patient a fragment of pathological tissue with the view of establishing the histological diagnosis of the disease with which he is affected." But the author has not attempted to give an ordered account of the histology of diseases of the larynx, nose, and ear, and the reader will look in vain for a systematic description of the pathological varieties, for instance, of neoplasms of the larynx or nasopharynx, or for a discussion of the types of bleeding polypus of the septum. The first chapter of this book is occupied by an exposition of the value of biopsy in making or confirming a diagnosis, and the thesis is abundantly proved and supported by reports of cases; but it would hardly seem necessary to labour this point, as though the microscopical examination of a fragment of diseased tissue were not already a routine procedure of everyday practice. An excellent, but too short, description of the histological technique is followed by a too lengthy account of the methods of removing pieces

of tissue from the various regions; this includes a description of direct and indirect laryngoscopy and cesophagoscopy, methods perfectly familiar to all workers in these regions. The final chapter contains results of observations on diseases of the various regions, and is not intended to be in any way a complete account of the pathology of the nose and throat. It contains a description of a number of interesting cases observed by the author, but is of small direct service for reference or as a source of information.

TESTS OF FUNCTIONS.

Funktionsprüfung Innerer Organe. By K. GLASSNER, L. R. GRATE, G. LEPEHNE, E. MAGNUS-ALSLEBIN, O. PLATZ, VAN DER REIS, M. ROSENBERG, and A. WEBER. Berlin: Julius Springer. 1924. Pp. 128. Gold marks 2.40.

THIS small volume is divided into eight chapters, each being written by a separate author. The first chapter deals with methods of investigating the functions of the heart by physical means, the second with electrocardiographic methods. A series of typical tracings are included. In the third chapter the functions of the stomach are treated in such an elementary fashion as to be devoid of interest. There is no account of the fractional method of gastric analysis, and, indeed, this chapter is in most respects out of date. The next chapter dealing with the lower sections of the alimentary canal is interesting in that it contains a fairly detailed account of test-meals and methods for the analysis of fæces. The following chapter, which contains an account of methods of investigating the liver, is without doubt the best in the book. It is quite up to date, and all the recent advances, such as Van den Bergh's reaction, are adequately described. The section upon renal function tests is again old-fashioned, and although a detailed account of Ambard's coefficient is given, the importance of blood analysis is barely mentioned. Tests for pancreatic function are dealt with in a sketchy manner. The authors have mis-read the names of several English workers. Thus the work of Bennett and Dodds is referred to as Parnett and Dodd, and that of Mackenzie Wallis as Wallis and Mackenzie. The final chapter deals in elementary fashion with the investigation of the vegetative nervous system by means of the action of drugs. No reference appears to be made to the work of Goetsch. It is unlikely that this volume, despite the imposing number of contributors to its hundred odd pages, will receive a warm welcome in this country.

THE EDUCATION OF BEHAVIOUR.

Second edition, revised and partly rewritten. By I. B. SAXBY, D.Sc., Senior Assistant in the Women's Education Department of University College, Cardiff. London: University of London Press, Ltd. 1924. Pp. 264. 6s.

THIS book sets out those modern principles of education which, requiring the teacher to study the why and wherefore of the actions of the child, make educational work none the easier but infinitely more interesting. Using the dynamic concept of psychology, the author draws upon W. McDougall and A. F. Shand for an account of the instincts and their development into sentiments and complexes, the use of the latter term indicating that the Freudian point of view is embodied in the general theme. We note incidentally that *impulse* is substituted for the word *instinct* because of the diversity of opinion in regard to the definition of "instinct," but to define impulse as an *inborn* tendency surely clashes with popular usage. After laying these foundations the author considers such matters as the growth of habits, the training of character, and the problems of adolescence. A useful example of the practical application of theory is found on page 234: "To ask a child 'Why do you steal?' 'Why do you lose your temper?' is to invite lies. The only true answer would be, 'I don't know; something in me makes me do it.'

But, if he thinks he ought to have a reason, he will find one, and since such a reason will make the outlet safer for the unconscious complex, he will probably feel convinced that he has found the true one."

The reader who fully understands the principles involved in this quotation has a useful grasp of modern psychology, and the book will aid him to obtain that grasp. Unlike many popular works on psychology, this book is soberly written and is not tendentious; it admirably fulfils its aim of helping not only teachers but all who have to deal with adolescent boys or girls.

WESTMINSTER HOSPITAL.

1. *Westminster Hospital Reports.* Edited by E. ROCK CARLING and HILDRED CARLILL. 1924. Vol. XIX. Pp. 299. 7s. 6d.

2. *Westminster Hospital.* An Outline of its History. By W. G. SPENCER. London: Henry J. Glaisher. 1924. Pp. 120.

OF these two books the latter is a reprint of the first article in the former, and a very good example of what a hospital history should be. Mr. Spencer begins by giving a topographical survey of Westminster from early times until the present day, which is particularly interesting, for few districts in the London area have seen more changes than Westminster. One of the most striking is the conversion of the singularly gloomy-looking Tothill Fields Prison and its site into the annexe of the Army and Navy Stores, the S.W. District Post Office, and Westminster Cathedral. Westminster Hospital took its origin from a meeting held on Jan. 14th, 1715, at St. Dunstan's Coffee House, Fleet-street, attended by Henry Hoare, William Wogan, Robert Witham, and Patrick Cockburn. Hoare was the then head of the well-known banking house; Wogan was a writer on religious subjects, and corresponded at a later date with Whitefield and Wesley. Witham was possibly a brewer, and Cockburn had been one of the assistant curates at St. Dunstan's. The four men founded a Charitable Society, the objects of which were defined in a pamphlet entitled, "A Charitable Proposal for Relieving the Poor and Needy and Other Distressed Persons." By 1716 the society had determined "that our principal care be confined to the sick and needy persons of St. Margaret's, Westminster." The result of this was that by Lady Day, 1720, a house in Petty France was opened as an infirmary, the first patient being admitted on May 11th. The infirmary was moved first to a site opposite the end of the present Caxton-street, then to some houses on the site of what is now Westminster Chapel; this was about 1733. In 1770 the name infirmary was changed to hospital. Here it remained until 1834, when the patients were moved to a new hospital erected on the present site.

Mr. Spencer gives a list with biographical details of the members of the medical and surgical staff from the beginning, together with all sorts of interesting details about the nursing and other domestic affairs of the hospital. These were by no means satisfactory in the early days, mainly owing to the fact that the governors, whose sole idea was economy—i.e., to pay the lowest wages and salaries, naturally got the worst type of service, and all kinds of petty pilfering occurred. Nursing was not really satisfactory until 1873, when the two Misses Merryweather were appointed lady superintendent and matron respectively. The Medical School was started in 1840. In 1923 the hospital was closed for renovation, practically reconstruction, and was reopened on July 15th, 1924. We have been able to give but the merest outline of Mr. Spencer's thorough account, but the whole of it is good reading. The remainder of the report comprises the usual statistical tables and sundry papers upon medical and surgical cases, of which, perhaps, the most interesting are: No. 4, An Analysis of Cases Coming Under the Jurisdiction of H.M. Coroner, &c., by Dr. Braxton Hicks, and No. 10, the Late Results of Gunshot Wounds of the Abdomen, by Mr. G. T. Mullally and Dr. Basil Price.

THE LANCET.

LONDON: SATURDAY, JANUARY 17, 1925.

QUERY DRUNK ?

AMONG the physical conditions investigated in courts of law, where medical evidence is of essential importance in determining the issues involved, two—namely, insanity and drunkenness—have a common feature which distinguishes them from other variations of normal health. To borrow a phrase from Sir JAMES PURVES-STEWART's lucid and valuable address on Acute Drunkenness, delivered before the Society for the Study of Inebriety on Tuesday last and published in THE LANCET this week, neither is "a simple clinical entity like a broken bone or a consolidated lung," as to which medical evidence must almost necessarily be accepted in favour of one side or the other. And as to the existence of insanity or of drunkenness—and they may occur in combination—lay witnesses have their say in most cases involving legal question, and give evidence upon which members of a lay tribunal, magistrates, jurors, or judges, consider themselves fully entitled to form independent and conclusive opinions in the light of their general experience of life. This introduces a difficulty of which medical witnesses should be fully aware, and which at times leads to conclusions which medicine cannot accept as satisfactory. Sir J. PURVES-STEWART's address should be read in conjunction with Dr. R. T. WILLIAMSON's paper on Mortality from Motor Traffic, which we publish also this week, when it will be realised, perhaps more fully than before, that the huge increase of motor-drawn vehicles which has taken place in recent years, and which shows every promise of continuing, has added fresh importance to the diagnosis of drunkenness, while introducing variations of the nature of the evidence required with regard to it. The man arrested a few years ago for being drunk when in charge of a vehicle had to meet an accusation in much less serious circumstances when his wheels were drawn by a horse, upon whose "horse-sense" he, and the public, to some extent relied; the man who now is brought before the court for drunkenness when driving a motor-car or lorry is more than occasionally required to stand a charge of manslaughter. It becomes now a charge of manslaughter if anyone has been killed through the alleged intoxication of a driver; it is potential manslaughter, visualised by the tribunal, if an arrest by the police is believed to have averted the offence of an intoxicated driver.

It is to be noted that the medical aspects and practical tests of acute drunkenness, as considered by Sir J. PURVES-STEWART, appear to divide the cases of drunkenness, presenting themselves for diagnosis through action of the police, into two main classes. In the one class the man charged may be the victim of physical conditions of which the police who arrested him were naturally unaware, conditions of which the symptoms are similar to those of intoxication by alcohol, but which, in fact, are due to entirely different causes. An extraordinarily apposite illustration of this sort of case is given by Sir J. PURVES-STEWART, furnished by a medical colleague. Here the driver of a car was suffering from chronic Eustachian catarrh and frequent labyrinthine vertigo. Having drunk a glass of gin and vermouth, which imparted to his breath the odour suggestive of alcoholic intoxication, he allowed the car which he was driving to mount the

footpath and come into contact with a foot passenger, having been compelled to avoid another foot passenger at a street corner. Conviction was followed by an immediate appeal and a rectification of the miscarriage of justice; and in this case there were full opportunity and means for setting right the excusable error into which the police had fallen. This will usually occur where the accused has a physical excuse to account for an accident. Analysis of the cerebro-spinal fluid, which Sir J. PURVES-STEWART finds the only, or at any rate the most convincing, way of proving the presence and absence of alcoholic intoxication is a drastic proceeding which can never become a popular test. Non-medical evidence for the elimination of alcohol as the cause of the symptoms observed will naturally be called to supplement scientific testimony, but such evidence is not always at the command of the man or woman brought before the magistrate as drunk and disorderly or incapable. In these cases reliance must be placed upon the experience of the police surgeon, who fully realises that the easy course of confirming the police view has often led to injustice. Where the accused can produce any evidence that what have seemed to the police to be the manifestations of intoxication are the results of physical default, we may be certain to-day that careful note will be taken of such a defence, which will be complete if the misleading symptoms persist after the period of alcoholism should have gone by.

The second class of case where careful consideration of the tests for drunkenness is required, and where increasing use of motor vehicles has multiplied the examples, is the accident occurring when the driver is not fully alert. A motor-driver has, to use Dr. WILLIAMSON's phrase, "a terrible weapon to control," and the danger in which he may place his fellow citizens at any time may be less apparent than it should be to his mind if he has consumed alcohol in far smaller quantities than would bring him under the notice of the police as a pedestrian or as the driver of a horse. The driver we are now considering is in normal health and not able to assign the symptoms observed in him to any previously existing condition not caused by alcohol. He is not so intoxicated, we may here also suppose, as to be helpless, disorderly, or quarrelsome. Nevertheless, his conduct as a motor-driver may call for the notice of the police. The customary story of such a case is that the driver vehemently disputes the justice of his arrest, and denies that alcohol has anything to do with the alleged irregularity in his conduct as a driver. He is brought to the police station, and having been seen by the inspector in charge, a police surgeon examines him, and perhaps some other doctor, possibly his usual medical attendant. In the meanwhile his condition in respect of drunkenness may have changed considerably. He may have grown worse than when he was arrested, or he may have shaken off to a great extent the supposed effects of what he has imbibed. He may have been excited and have become worse, or he may have grown calmer. In any case, the medical man who examines him is not likely to find him as he was when first taken into custody, and his condition is not that of a man who has been recently helpless from drink. In these circumstances the foundation of a definite opinion by a medical practitioner may be difficult, and its enunciation is not rendered easier by the attitude of some magistrates, who dislike explanatory phrases, and expect a witness to answer "Yes" or "No" to the question "Was the prisoner drunk?" while neither magistrate nor doctor is agreed upon any definition of drunkenness.

SIR J. PURVES-STEWART makes it plain that it is difficult to supply a definition of drunkenness satisfactory to medical men and at the same time convenient of application before a lay tribunal. Moreover, drunkenness which a magistrate would rightly condemn in the case of the driver of a car or lorry, differs from that which is brought to his notice in other connexions. On the whole, in view of the difficulty of defining and proving, or disproving, drunkenness in its medico-legal aspects, it is well that we can accept the estimate that in nine cases out of ten the policeman's diagnosis is correct—we might even fix the proportion of right decisions by the constable at a higher figure. The matter deserves serious consideration when we find how steadily and how rapidly the number of fatal accidents due to motor vehicles has increased and is increasing. Mistakes may be made and it may, at times, be the function and the privilege of the medical witness to prevent or to correct them by careful diagnosis. At others it will be his duty to see that men who drink intoxicants when they know that they have to drive should have their condition fully explained to the authorities responsible for the public safety. Dr. WILLIAMSON suggests that motor-car drivers should be fined for every fatal accident. We do not endorse this as a practical remedy, nor is it, we think, consistent with the generally accepted view of justice. We are more in accord with his opinion that all drivers should abstain from alcohol during their hours of duty, and should be required to produce a certificate that they are temperate as regards alcohol. That they should be total abstainers strikes us as a counsel of perfection impossible to carry out. The enforcement of sobriety among drivers by all possible means would tend to the protection of the public and would be possible in some degree in a class which is already compelled to be officially licensed. In any case, the prevention of charges of drunkenness is of an importance to the public at least equal to that of the accurate diagnosis of intoxication in the individual accused.

THE PANEL PRACTITIONER'S RIGHT OF APPEAL.

SOME misunderstanding has arisen regarding the scope of the new rules for appeal under the National Health Insurance Acts which came into force at the beginning of the year. The amended form of Rules 1 to 11 of Order LV B of the Supreme Court, printed in THE LANCET of Jan. 3rd, refers only to appeals from ministerial decisions under Section 89 of the National Health Insurance Act, 1924, on questions relating to the liability of employed persons to be insured or to the amount of weekly contributions payable. These Rules do not in any way affect the important question of the panel doctor's right of appeal to the Courts against ministerial decisions affecting him, or the equally important question of his right to require a case to be stated for the consideration of the High Court. The position on these matters still remains as follows. Against the infliction by the Minister of a pecuniary penalty there is no right of appeal and no means of questioning the Minister's decision, provided that the Minister in arriving at his decision has followed the prescribed procedure. It will be recalled that the Minister's unrestricted power in this respect was recently brought into prominence by a case in which the Minister inflicted what was very widely regarded as the excessive penalty of £1000. Against any decision given by the Minister in his judicial capacity on an appeal from a decision by an insurance committee,

there is also no right of appeal, neither can an appeal be lodged against what the Department regard as the administrative act of the Minister in removing a doctor's name from the panel. It is true that the provisions of the Arbitration Act, 1889, are applied to the hearing or inquiry which precedes the latter two classes of ministerial decision, but as regards opening the doctor's approach to the Courts the effect of this is no more than to provide that at any stage of the proceedings the Minister may, or, if directed by the Court or judge, must state as a special case for the opinion of the Court any question of law arising in the course of the proceedings.

From the very inception of the National Health Insurance Act of 1911 the medical profession have considered that the opportunity afforded to the doctor to approach the Courts has been inadequate. Prior to 1913 the view was strongly pressed that the right of final appeal to the Courts against ministerial decisions should be widely recognised. Subsequently this view was somewhat modified. It was recognised that such rights could not be unilateral and would have to be extended to insured persons, approved societies, and insurance committees, with the resultant risks to the doctor of expense and undesirable publicity; it was also felt that the Minister, being specially conversant with the whole subject-matter and alive to the importance of adequate continuity in decisions, might be the most suitable tribunal for deciding the majority of cases. There remained, however, the belief that there should be some further right of appeal against the Minister's decision to remove a doctor's name from the panel, and the recent case to which reference has been made revived the demand for some check upon possibly arbitrary or unjust action by the Minister in the infliction of a pecuniary penalty. The present view of the central representatives of the medical profession on these matters is set out in the draft memorandum of the evidence to be placed before the Royal Commission on National Health Insurance by the British Medical Association. As may be seen from the summary of this memorandum, which we printed last week, the view is that, while the insurance doctor might justly be made liable to penalty for the wilful charging of unauthorised fees and for such general conduct as is held to be detrimental to the interests of the service, and might be subject to serious official action for the making of wilfully false statements in connexion with the records, reports, and certificates which he has undertaken to furnish, general questions of supposed neglect or lack of success or improper behaviour on the part of the doctor should be solved by the exercise of the patient's right to change his doctor at any time, just as cases of unreasonable conduct on the part of the patient should normally be dealt with by the doctor's right to notify that he no longer desires to be responsible for the case.

If these principles are adopted it is thought that the present machinery should not on the whole be inappropriate to meet the majority of cases, if two further safeguards are provided. These are: (a) in cases of infliction of penalty, an appeal to the Courts should be possible, not only on the ground of improper procedure, as at present, but also on the ground that the penalty inflicted is out of proportion to the offence; (b) in cases of proposed removal from the panel the doctor should have the right of appeal to a duly constituted central professional committee, and that not until that committee advises the course should the Minister be able to remove a doctor's name from the panel. The General Medical Council would be the natural tribunal to hear such appeals if to do so came within its statutory scope.

UNCALLED-FOR APPENDECTOMY.

How often has the vermiform appendix suffered the fate of the innocent scapegoat and been cast into the wilderness for the sins of the abdomen? Dr. Henry Wald Bettmann, of Cincinnati, in a paper on Diagnostic Errors Leading to Uncalled-for Appendectomy,¹ places the figure high, and he supports his contention by many quotations from published articles, mainly American, which, if they represent the state of affairs prevalent at the moment in the United States, show the need for a very drastic revision of the diagnostic symptoms of appendicitis. "In 1920 Hugh Cabot stated that in large surgical clinics hardly a day passes on which patients who have had their appendices removed without relief do not present themselves. The following year R. F. O'Neil informed us that about 25 per cent. of the patients in the Massachusetts General Hospital who had ureteral calculi had had operations on their appendices or the abdominal organs before a correct diagnosis was made. In 1922 S. A. Chalfant called attention to what he called a notorious fact that the ultimate results of operations for chronic appendicitis are among the poorest in surgery." The justification for the operation lies, Dr. Bettmann is careful to point out, not in the pathological condition of the appendix as found by the surgeon or pathologist, but in the clinical results obtained by the operation. He sets out clearly the difficulties attaching to the diagnosis of the chronic appendix and particularly refers to the chances of error in diagnosing appendicitis from subjective symptoms alone (right iliac fossa pain) in the absence of previous attacks.

There is, however, a very real distinction to be drawn between difficulty of diagnosis and want of care in examination. Dr. Bettmann's estimate that two-thirds of a series of 170 cases unsuccessfully operated on had never been carefully studied before the operation would seem to point to the latter cause rather than the former; but one cannot help believing, and indeed hoping, that Dr. Bettmann has painted the picture in rather lurid colours to press home his point. To us in this country such a statement is frankly astounding. It may be, however, that there is less risk of inadequate study on this side of the Atlantic, where the patient is rarely operated on by the medical man making the first observation, and indeed in our hospitals patients are most carefully examined by three or four different experts before the diagnosis is decided. Further, we place less reliance upon the X ray diagnosis of the condition. Dr. Bettmann does not mention the confusion which may arise in the differential diagnosis of visceroptosis and appendicitis, and a statement which he makes gives a possible clue to some of the unenviable results he records. He says:—

"In the series of cases which form the basis of this paper, I have accurate records in 127 patients of the right iliac physical findings from one to five years, or, in a few cases, even longer, after the appendectomies had been performed. In 78 cases the incision had been made in the right iliac region; in 49 cases the incision was made in the median line. Of the 127 patients, 55, or 43 per cent., still had definite tenderness at McBurney's point quite as marked as we ordinarily see in unoperated patients. It is astonishing to learn that persisting right iliac tenderness was even more common in the patients with a median incision than in those with a right-sided incision; 24 out of 49, or nearly 50 per cent. in the median cases; 31 out of 78, or 40 per cent., in the other group. A larger series of cases may possibly somewhat modify these proportions, but it is as important as it is interesting to learn that more than 40 per cent. of patients after unsuccessful appendectomy manifest tenderness in the right iliac region. It may be that the removal of the appendix creates a right iliac tenderness which did not formerly exist. Future observations are needed on this point."

It is very probable that in many of these cases the trouble is really visceroptosis, or at any rate ptosis

of the cæcum and not appendicitis at all. It is true that enteroptosis is occasionally, perhaps frequently, associated with abnormal, generally fibrotic, appendix, but the changes in the appendix are secondary, and removal of the appendix can do little, if anything, to cure such a case.

Epigastric pain is the essential fact in so-called appendix dyspepsia, but this very point may lead to another source of error—namely, the diagnosis of appendicitis while overlooking the existence of the real cause in the upper abdomen, whether it be a duodenal or gastric ulcer or a cholecystitis with or without gall-stones. Many surgeons in this country in making the relatively rare diagnosis of appendix dyspepsia open the abdomen above the umbilicus, thus securing a good view of the upper abdominal organs and avoid the risk of overlooking the real cause of the trouble. If the anæsthetic is well given there should be no difficulty in removing the appendix through such an incision. Considering the appendix more from the histopathological point of view than from the clinical, Prof. Oscar Beutner, of Geneva, deals² with the indications for appendectomy in the course of gynæcological laparotomy. His observations are based on a series of 1400 laparotomies which he performed personally between the years 1907 and 1922. His conclusion is that the removal of the appendix during the course of a gynæcological laparotomy should be based on pathological signs in the organ, and that the routine removal of the appendix in every case of laparotomy is not to be recommended. He quotes with approval the words of H. Vulliet: "Let us leave the appendix in peace, even if its size or its form do not please the eye," and adds the pertinent corollary that it is surprising what a lot of rough handling the appendix will stand.

A TENEMENT VENTURE.

An attempt is being made to solve the slum problem in Bath on lines which deserve to be more widely known. The slum problem in Bath is, and has been for years, a particularly serious one. Several of the areas are below flood-level, all contain houses falling to pieces, insanitary, and terribly overcrowded, and there were in 1923, when this venture was started, 400 houses which were actually condemned as unfit for human habitation. The families occupying them had, however, in most cases no alternative to remaining where they were, as there was no other accommodation to be found. Realising the position a small group of Bath citizens conceived the idea of acquiring, near the slums but in a better neighbourhood, a large empty house—part of which had, in fact, been a public house—and of turning it into a number of tenements. For this purpose appeal was made for funds to purchase and reconstruct the property, and most of the needed money was obtained in smaller or larger donations. Just over a year ago the new tenants moved in, nearly all of them families with young children and all of them from badly overcrowded or insanitary dwellings. There are now eight families in the house; the rents vary from 4s. 6d. to 10s. per week according to number and size of rooms, and the venture is regarded as in so sound a financial position that the committee is on the look-out for another house to use in the same way. The aim throughout has been twofold: to relieve some of the congestion in the worst parts of the city and to provide homes of a decent and adequate nature for some of those who have hitherto had to live in the utmost squalor. The annual meeting of the British Medical Association, which is to take place at Bath from July 21st–24th, will have a section of Medical Sociology under the presidency of Dr. C. E. S. Flemming, of Bradford-on-Avon. We commend the Bath tenement venture to the sympathetic attention of this section.

Annotations.

"Ne quid nimis."

WEATHER AND MORTALITY.

IN the current registration week respiratory diseases accounted in London for 520 deaths, only 56 of which occurred between the ages of 5 and 55. The age-group 0-5 claimed 325 deaths, and the age-group 55-upwards, 139 deaths. Taking the summer week of six months previous, the corresponding figures were: Total 154, 0-5 group 92, 5-55 group 20, 55-upwards 42. It has long been recognised that weather conditions obtaining in the winter months are accompanied by an increased mortality from respiratory diseases—namely, bronchitis and pneumonia. Thirty years ago the late Dr. James B. Russell, of Glasgow, in his treatise on "The Evolution of the Function of Public Health Administration," wrote a strong condemnation of smoke and its ill-effects, and concluded that a high pulmonary mortality was caused by the combination of fog and low temperature. Proof, however, of the exact part played by the several meteorological factors which might be concerned in a high mortality has only recently been forthcoming, and for this our thanks are due to the statistical method, and in particular to two papers recently issued by the Statistical Department of the National Institute for Medical Research. In the first of these, which appeared in our own columns,¹ Mr. W. T. Russell dealt with the influence of fog on mortality from respiratory diseases among children (0-5 years) and adults (55 years and upwards) in the boroughs of Islington and St. Pancras in each week from October to March for 27 years beginning with 1870; the analysis was confined to these age-groups, as their mortality from respiratory diseases embraces 70 per cent. of the total deaths from these diseases. He found that the trend of deaths among children was altogether different from that among adults. The graph of the former starts from a minimum in October and reaches its maximum in the last week of November, and then falls to what is practically a fixed level for the remaining weeks. On the other hand, the curve for adults like that for children starts at a minimum, but goes on increasing with the exception of a very slight depression in the fourth week of December, and attains its maximum in the first or second week of January. It was observed that the period of maximum fog did not coincide with the maximum of deaths. It remained to investigate if the fog required the conjunction of some other meteorological factor; rainfall had no influence, but it was found that if the prevalence of fog was associated with a low temperature and frost, then the respiratory death-rate was influenced very considerably in adults; this effect was not evident in the case of children. Dr. M. Young's paper² helps us in the case of the children. He deals very fully with the influence of monthly and weekly temperatures (mean and minimum), of monthly and weekly relative humidity, and of monthly and weekly mean rainfall upon the mortality from respiratory diseases in children under 5 years, for a period of from 40 to 50 years in the cities of London, Glasgow, Edinburgh, Aberdeen, and Dundee; he studies also the relationship between the death-rates for these diseases in the registration counties of England and Wales in the decennia 1901-10 and 1891-1900, and their mean annual temperature and mean annual rainfall. Dr. Young finds that the lower the mean temperature the greater the fatality from bronchitis alone or from bronchitis and pneumonia summed together, and also that the mortality is most intimately related to the mean temperature of the preceding week. As suggested by Dr. Leonard Hill, the cold weather probably compels children to remain indoors in stuffy,

over-heated rooms, where infection is intensified and health weakened by heat stagnation, by a lowered metabolism, and by want of sunlight. Rainfall had no influence on the death-rate for respiratory diseases in children, nor had humidity except perhaps in Glasgow. Here there was some suggestion of the existence of a direct association—the moister the atmosphere the higher the death-rate from bronchitis.

COST OF SANATORIUM TREATMENT.

THE Ministry of Health has issued its second annual analysis of the costs of treatment at a large number of sanatoria and other residential institutions for tuberculosis, and thereby does undoubted service to the economical and efficient management of those institutions. The Ministry itself makes no comment on the figures beyond suggesting that in some cases further consideration might be given to the cost of provisions, the proportion of staff to beds for patients, and the advantage of keeping the beds constantly occupied, if need be, by taking patients from other authorities. Most of the factors governing costs are given in such detail that it should be easy for boards of management and medical superintendents to judge if their institutions are being managed economically.

The figures cover the year ended March 31st, 1924, and represent costs per patient per week. Some sanatoria, especially those recently built, are burdened with heavy loan charges, ranging up to 28s. per patient per week. If loan charges, rent, rates, taxes, and insurance are excluded, as being more or less outside the control of the management, more useful comparisons are possible with the remaining costs. Thus, if the 24 larger sanatoria, mainly for adult pulmonary cases in England, are taken, each containing 100 beds or more and each controlled by a local authority, the average cost is 39s. 3d., which is only about 1s. less than the previous year. The extremes are 32s. 9d. and 49s., but only five are below 36s., and two over 43s. 6d., so that on the whole there is a considerable degree of uniformity. Local conditions, such as the planning of the institution or its adaptation from other uses, often determine the standards of staffing and fuel consumption. Other four large institutions which may definitely be classed as hospitals for advanced cases cost on the average 48s. 7d., which is the same figure as last year. It would be an advantage if the Ministry gave cost of food of patients and staff separately. At present it gives the cost of provisions for patients and staff together, divided by the number of patients. Hence, in any comparison the proportion of staff to patients has to be taken into account. The average for the larger sanatoria is 1 nurse to 6½ beds occupied. The wide range, 1 to 5 to 1 to 12, suggests that standards of staffing are far from uniform. On the basis stated, costs of food average 14s. 7d., in few cases being over 16s. or less than 13s. The lowest figure is 10s. 11d., which in a large institution with one nurse for every five patients can scarcely be correct. A figure of 14s. 7d. would correspond approximately with a cost of 11s. 3d. per week for a patient's food alone. In the smaller sanatoria belonging to local authorities, and in sanatoria belonging to voluntary bodies, the average total cost is 5s. or 6s. higher than for the large sanatoria, and in these the range of costs is considerably wider. Cost of food is generally higher, ranging in one institution up to 27s. 7d. in 1923. It is clear that great economy is possible in such a case. In institutions for children the cost of food ranges ordinarily from 8s. to 10s. From the table it is possible also to compare the average salaries paid to the nursing staffs of the different institutions. In several the average ranges between £40 and £50 a year, while at the other end of the scale it rises to £80 to £85, or even in one extreme case—a very small institution—to £100. It is also interesting to find that in few sanatoria do the drugs and medical appliances cost as much as 1s. per patient per week.

¹ THE LANCET, 1924, ii., 335.

² Journal of Hygiene, 1924, xxiii., 151.

Although there are considerable differences between institutions apparently alike in the proportions of early, intermediate, and advanced cases, it is safe to infer from the figures published that many institutions have quite different standards from the others in regard to the classification of these groups of cases. This defect will doubtless improve when the classification put forward by the Ministry becomes more widely employed.

THE POLICY OF THOROUGH IN SANATORIUM TREATMENT.

THE report of the Vejlebjerg Sanatorium for 1923, the year of Prof. Saugman's death, shows that in spite of the loss of its distinguished head it continues as a pioneer institution, testing every new therapeutic measure likely to be beneficial. Of the 103 patients discharged during 1923, after an average residence of 208 days, only 12 belonged to the first stage of the disease, and as many as 72 to the third stage. And yet 74 patients were discharged as improved or "relatively" cured. A clue to these good results is to be found in the extensive use of lung collapse treatment and actinotherapy. As many as 33 patients were selected for artificial pneumothorax treatment, thoracoplasty was performed in 11 cases, thoracoscopy with cauterisation of adhesions in 13, and phrenicotomy in one case. Carbon arc-light baths were given in 27 cases, quartz mercury baths in 10, sun baths in four, and X ray treatment in six cases. Of the 66 patients who were sputum-positive on admission as many as 19 were sputum-negative on discharge. A comparison of a report like this with any typical sanatorium report 15 or 20 years ago cannot fail to show how great is the progress that has been made since the days when sanatorium treatment consisted almost exclusively of rest, graduated exercise, dieting, and exposure to inclement atmospheric conditions.

VACCINATION FOR WHOOPING-COUGH.

WRITING on the Treatment of Whooping-cough in our own columns two years ago Dr. T. Izod Bennett said¹: "Vaccine treatment in whooping-cough, whether prophylactic or curative, is logical and harmless: it is not at present possible to say that it is invariably beneficial." Since then Dr. A. H. Meyer, Dr. M. Kristensen, and Dr. E. Sørensen have carried out extensive investigations with a whooping-cough vaccine in numerous Danish hospitals, and a report on these, as well as the experience of general practitioners in Denmark and the Farøe Islands, has now been rendered available.² The Danish vaccine was prepared from a 48-hour old blood-agar culture of Bordet-Gengou bacilli, of which there were about 10,000 million per cubic centimetre. It was injected subcutaneously, three injections being given at intervals of four days, the doses at each injection being 0.5, 0.7, and 1 c.cm. respectively. At one hospital intramuscular injections were given on five successive days, the doses being 0.1, 0.2, 0.4, 0.8, and 1 c.cm. respectively. The vaccine was given both as a prophylactic and as a therapeutic measure, and the results obtained were classified according as the vaccine was given as a prophylactic or not, and according as it was used in hospital or general practice. Questionnaires were addressed to 109 doctors who had been supplied with this vaccine, and replies were obtained from 69. The verdict was decidedly favourable on the whole, although not unanimous. All the practitioners in the Farøe Islands reported favourably after an experience of about 2100 cases. It was observed that the disease was less severe in children given prophylactic injections than in those who acted as controls. In some cases the vaccine did not prevent the development of the disease, which did, however, seem to run a definitely milder course, thanks to this procedure. When the vaccine was given for the first time early in the disease

it also seemed to have a beneficial effect, but when the disease had fully developed there was a divergence of opinions as to the therapeutic value of the vaccine. Late in the disease it would seem to be practically useless. The authors refer to complement-fixation tests in six children, none of whom had had whooping-cough, and only three of whom had been vaccinated. As was to be expected, the three children who had not been vaccinated gave no complement fixation with whooping-cough bacilli, whereas the three vaccinated children gave complement fixation which reached its maximum eight days after the third injection. Though the authors' report is definitely favourable to this vaccine, notably when it is given as a prophylactic to children exposed to infection with whooping-cough, they admit that there may be much room for improvement in such directions as the preparation of the vaccine, its dosage, and the time of administration. There may be various types of Bordet-Gengou bacilli, and the differences in the results of vaccine treatment may partly depend on our still imperfect knowledge of these still hypothetical types. Another factor which may influence the action of this as of other vaccines is its age. Larger doses at shorter intervals might possibly increase the percentage of successes.

TWO CENTURIES OF GUY'S HOSPITAL.

ALTHOUGH Guy's is far from being the oldest of the London hospitals, it took its place, almost from the beginning and as of right, beside its two ancient and famous predecessors. The doors of this noble foundation, which last week commemorated its two hundredth anniversary, were hardly opened before the whole of its 400 beds were occupied—an unmistakable indication of the extent of the need to the alleviation of which Thomas Guy devoted the bulk of his great fortune. On Jan. 6th, 1725, he lay dead, robbed by a dramatic stroke of fate of the crowning satisfaction of watching the fruition of a great idea. By the standards of longevity of his day he was a venerable old man—for that matter, indeed, the span of life has even now not been lengthened sufficiently for 80 to be thought of as anything but a "good old age." Length of years and abundance of opportunity must needs have had their influence upon the acquisition of the £330,000 which he accumulated, two-thirds of which he set aside for the endowment of his hospital. The bases of his fortune were curiously mixed. Founded upon the sale of Bibles it was reinforced by speculation in sailors' pay-tickets and consolidated by fortunate operations in that South Sea stock which brought ruin to so many who were less prudent or more avaricious. There is no good reason to suppose that Guy was other than an honest and honourable man, and assuredly he did not accumulate money for his personal comfort or the gratification of social ambition. His self-denial was directed in the main to the furtherance of a great act of charity the fruits of which are still with us, to say nothing of the charity which he dispensed in his life-time, and his personal service as Member of Parliament for his mother's native town of Tamworth, still dominated by that grim castle of the Marmions with which he must have been well acquainted.

The most precious faculty of ancient and virile institutions is their power of renewing their youth, of adapting themselves to new needs and novel conditions. The great London general hospitals are remarkable examples of this power and of its successful exercise. For generations past they have been faced by tasks which have steadily grown in magnitude and complexity—tasks, moreover, which have consistently outrun the material means of performing them. At the time it may well have seemed that, in the words of his epitaph, Guy's foundation in its generosity "rivalled the endowment of kings," but as men grow in numbers and knowledge and ever ask more of life, the value of money sinks. In the course of its history Guy's has had other and great

¹ THE LANCET, 1923, i., 198.

² Acta Paediatrica, vol. iv., Fasc. 1, 1924.

benefactors, notably William Hunt, who, a little more than a century after the death of the founder, bequeathed to it a fortune hardly inferior to that amassed by the bookseller's apprentice, yet to-day its expenditure exceeds its assured income by close upon £2000 a week. Much of this great outlay has been necessitated by the determination of the governors that the hospital shall never fail to respond to the demands upon it for the means of cure, and still more for the means of prevention. Very soon Guy's will celebrate another event not less important than the provision of the hospital itself, for this is the centenary year of the medical school which has produced an almost unrivalled series of great physicians and surgeons, has incalculably reduced the sum of human misery, and exercised a decisive influence over the development of medical education. The public is apt to forget, or to lay insufficient stress upon, the vital importance of the functions of teaching and research which the great hospitals have laid upon themselves—functions which ever grow more momentous. It is, therefore, well to emphasise the fact that of the £200,000 which the governors of Guy's Hospital are just now asking the country to provide, £40,000 are accounted for by the debt on the medical school, while £100,000 are mainly represented by the cost of providing such "modernities" as X ray, light, and massage treatment, and better accommodation for nurses. Upon the actual maintenance of the hospital there is a debt of more than £50,000. That Guy's is not in the habit of appealing for great sums is a testimony to the excellence of its management no less than to its good fortune in attracting substantial benefactions. Only once before has it begged on a large scale, chiefly by reason of the lack of income caused by agricultural depression. The £100,000 for which it then asked was obtained, and we cannot doubt that the larger sum that is now urgently necessary will be forthcoming before the close of the bi-centenary year.

A great hospital such as this is not an institution local to London. In many directions its work benefits the entire kingdom—it would, indeed, be no exaggeration to say that those benefits extend, more or less directly, far beyond the bounds of the Empire. This is especially true as regards its always growing activities in the prevention of disease and the discovery of methods of cure. Thus its appeal is as wide as the results of its work. Guy's Hospital has steadfastly renewed its youth in the past, and it is its barest due that it shall not suffer because it has interpreted its duty in so broad a spirit and with so receptive a mind.

DEVELOPMENTS IN PUBLIC HEALTH TEACHING.

WE have referred recently to some interesting developments in research which are being made by the London School of Hygiene and Tropical Medicine at the present time in coöperation with the authorities of Southern Rhodesia, with the Zoological Society in this country, and otherwise. We learn that on the teaching side of the school the question of the practicability of easy developments in the teaching of public health is being thoroughly explored. The tropical division of the school (the Old London School of Tropical Medicine, at Endsleigh Gardens, Euston), which was originally founded by the late Sir Patrick Manson, was taken over by the new body on August 1st, 1924, and the new course in parasitology for the Diploma of Public Health is being given by the heads of some of the departments of this school.

Developments in the general public health teaching undertaken by the school will, it is anticipated, be made so far as is practicable, having regard to the accommodation and financial assistance available pending the erection of the new building. In this connexion an interesting stage has been reached, as five architects—selected by the board of management

in consultation with their assessor, from those architects who have had special experience in laboratory construction—have been invited to submit, in competition, designs for the building which is to occupy the site in Gower-street acquired some time ago for the purpose. It will be remembered that the funds for the provision of the new building and for its equipment are being provided by the International Health Board of the Rockefeller Foundation. We understand that the building and site will cost well over £100,000, and that the accommodation to be provided, apart from the basement, will extend to 100,000 superficial feet of floor space. A special feature of the plans will be the large amount of space devoted to the purposes of the museum. In its construction, and in its equipment, it is anticipated that the new school will realise the high hopes of those who have been concerned in its provision, and prove to be a worthy embodiment of the benefaction of the Rockefeller Foundation. We may add that the present staff of the London School of Hygiene and Tropical Medicine have every confidence in the success of the final scheme under the able directorship of Dr. Andrew Balfour. Since the institution of the new régime there has been no falling off in the number of students attending the course; on the other hand, the size of the classes is rapidly increasing. During the autumn term of 1924 a record number of over 70 post-graduates attended, while the class just assembled is much larger than what is usual at this time of the year.

The standard of knowledge necessary to acquire the D.T.M. is causing some anxiety to the teaching staff, it being necessary at the present moment to condense a large amount of instruction into a three months' course, so that consideration is now being given to the feasibility of extending the duration of the courses in order to keep pace with the rapidly extending field of tropical medicine and hygiene. One of the most important activities of the school lies in the Tropical Diseases Library; this, in conjunction with the Tropical Diseases Bureau, has now developed to a very considerable extent. It is hoped so to equip it that it may constitute the standard library for all workers in tropical medicine and hygiene in the metropolis. The library is now being utilised by a number of outside workers as well as by students attending the course.

THE TEAM SYSTEM IN PHYSICAL TRAINING.

A CIRCULAR on Physical Training (price 1d.), just issued by the Board of Education as a supplement to the Board's Syllabus of Physical Education (1919), marks the steady drift away from the artificiality of the Ling system to the more natural form of exercise in the shape of play with educational value. The lack of emotional content in the Ling system has always been noticeable, and the value of the herd instinct as a means of adjusting the individual to his social surroundings has been demonstrated convincingly by Sir Robert Baden Powell in the Boy Scout movement. A system of physical exercises utilising this instinct must have great educational value. The team system has been developing of recent years in English and New York schools, and has now taken a proper place in the educational curriculum for older boys and girls. The practical advantages of the system are thus summarised in the circular:—

(1) Greater variety in the work can be obtained by giving the teams different exercises (particularly recreative exercises) and games; (2) the children are able to get more practice in the exercises and to take a more active part in the games by working in smaller groups; (3) much time is saved in exercises in which only a few children can take part at once, by setting the teams to work separately; (4) it is often possible to teach some new exercise or game to one or two teams at a time, while the other teams practise what they already know, and in this way to give more attention to the instruction of individuals than is possible when the whole class is taken together; (5) the permanent grouping makes for quickness, order, and efficiency in class formations, and generally for a more flexible and rapid handling of the class; (6) the keen

rivalry that may be encouraged between the teams adds greatly to the interest of the work and stimulates proficiency.

For the egocentric young child it is of little use, as is pointed out in the circular, but with the rapid growth that precedes adolescence its value runs up to a peak. The team system in schools is bound to be of benefit to the future community not only in the physical health produced by bodily exercise, but also in the mental health which is an indirect result of striving after a well-established aim.

THE HONOURS OF A SURGEON.

THE memory of Joseph Lister is being kept green. Two years ago the Canadian Medical Association decided to have an address in his honour at every third annual meeting. The committee appointed for the purpose chose Dr. John Stewart to deliver the first oration, and we have just received a reprint of this admirable address.¹ It was a happy choice, for Dr. Stewart was one of Lister's dressers and also a personal and life-long friend. The oration gives an account of Lister's life and work which may be commended to such, if any there be, who are ignorant of the marvellous change which took place in the theory and practice of surgery owing to Lister's labours and his intuition in grasping the meaning of Pasteur's researches. Lister became a Fellow of the Royal Society in 1860 and was its President from 1895-97. We cannot recollect if there is any living surgeon, except Sir Watson Cheyne, who holds the Fellowship in right of his position as a pioneer in surgery, a fact which suggests the inquiry whether the remarkable qualities which lead to success in a surgeon's career may not sometimes obscure his scientific attainments in the eyes of the Council of the Royal Society. During mid-Victorian days a number of surgeons were Fellows. In Lister's case the scientific recognition long preceded his popular acceptance. We are glad to note that Sir Rickman Godlee's life of Lord Lister has reached a third edition,² even though, as we learn from the preface, there is little difference between this edition and the two former ones. The new matter includes a new portrait and facsimile of an autograph letter, together with a postscript containing a short summary of the present method of treating wounds, including experience gained in the late war. The most noticeable remark concerns catgut ligatures, of which Sir Rickman Godlee says: "We may fairly hope that Lister's prodigious effort to discover a thoroughly satisfactory catgut ligature will ultimately lead, if it has not already led, to the production of an easily obtainable article, properly standardised as regards texture and absorbability, and beyond suspicion on the score of sterilisation." These are little additions, but all such minutiae are welcome in a well-loved portrait.

AMBULANCES AND ACCIDENTS.

AT a recent inquest Dr. Waldo, the coroner for the City and Southwark, once more called attention to the insufficiency of the ambulance service in the County of London. In relation to its size the City is so well supplied with ambulances and stations that a call is responded to, on the average, in less than three minutes; in the area of the County Council the average is seven minutes and a half, but in the case into which Dr. Waldo was inquiring, the delay, owing to the nearest ambulance being already engaged, was 14 minutes. Obviously ten ambulance stations are utterly inadequate to the needs of an area of 115 square miles. It is true that an eleventh will be ready at the end of the present month and that two more will be opened in September, but even 13 stations bear no

reasonable proportion to a need which has grown with startling rapidity. Last year the calls received by the London County Council ambulance service were 15 times as numerous as in 1915, owing to the increase of motor traffic and the perilous congestion of every great thoroughfare. The County Council being solely responsible for providing succour in street accidents, the police are unable to avail themselves of the help of the ambulances and trained officials of the Metropolitan Asylums Board or the St. John Ambulance Association. It would appear that the Asylums Board steps in only in case of sudden illness, while the St. John ambulances are reserved for street processions and special occasions. The whole question was discussed last year at a conference called by the Minister of Health, attended by representatives of the London County Council, the Metropolitan Asylums Board, the Metropolitan Police, and the Home Service Ambulance Committee of the Joint Red Cross Council. It was then decided that all street accident cases within the area should be dealt with by the County Council and the City of London Ambulance Services. The view of the Home Service (Red Cross) Ambulance Committee is, we understand, that they cannot usefully coöperate in this work, though in a matter of urgency any Red Cross ambulance would be available. Whatever may have been the advantages of such a distribution of responsibility when the arrangement was made some years ago, it has clearly become archaic. Coördination is now urgently needed. Four public ambulance authorities with distinct functions and apparently responsible only to themselves are hardly suggestive of comprehensive and business-like organisation. The organisation is, however, defective mainly because of the heavy pressure that has been applied to it with little warning—last year the ten County Council ambulance stations dealt with more than 30,000 calls. The provision of a larger number would, no doubt, be expensive; but nothing is so costly as avoidable suffering and unnecessary loss of life.

The Services.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. W. F. Ellis is placed on the half pay list on account of ill-health.

The undermentioned Majs. to be Lt.-Cols: Bt. Lt.-Col. H. V. Bagshawe, vice Lt.-Col. W. F. Ellis, to half pay. R. J. Franklin, vice Lt.-Col. H. S. Anderson, to ret. pay.

TERRITORIAL ARMY.

Capt. J. F. Edmiston to be Maj.

Capt. H. A. Lucas resigns his commn. and is granted the rank of Major.

ROYAL AIR FORCE.

Flight Lt. J. Speak (Capt. Dental Surgeon, General List, Army) relinquishes his temporary commission on resigning his commission in the Army.

INDIAN MEDICAL SERVICE.

The King has approved the promotion of Lt.-Col. R. W. Knox to Colonel.

THE LATE DR. DOUGLAS HOLROYDE.—Douglas Holroyde, M.A., M.B., Ch.B. Camb., who was formerly in practice in Barnsley, died on Jan. 3rd at Orrest Foot, Windermere, aged 48, after a long illness. He was the third son of Mr. Alfred Holroyde, of Halifax, and a brother of Dr. Gerald M. C. Holroyde, of Windermere. After his undergraduate career at Cambridge, he became M.A. in 1903, and pursued his medical studies at Cambridge, Leeds, and Dublin, graduating at Cambridge as M.B. in 1908. At Cambridge he was an Exhibitioner of Trinity College. In his younger days he was an ardent rock climber. Up to the time of his illness he was an honorary surgeon at Beckett Hospital, Barnsley, and had previously held the posts of house physician at the Leeds General Infirmary and resident medical officer at the Sanatorium for Consumption, Leeds.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CV.—BURNS AND SCALDS.

BURNS and scalds are injuries with which almost every practitioner may have to deal, and which offer him an exceptional opportunity both for the immediate relief of his patient and for the prevention of subsequent disfigurement or deformity. Yet there are few conditions in which opinions are so varied as to the best methods of treatment, perhaps one indication of the immense importance of individual attention in these cases.

In an extensive burn the first consideration is undoubtedly shock, which may be very severe, and depends on the extent of the surface involved rather than upon the depth of the lesions. If one half of the surface of the body is involved the injury will certainly be fatal, but a much smaller burn over the abdomen or thorax may have a similar result. The pain and shock are best combated by a substantial injection of morphia, varying from gr. 1/12 in an infant to gr. ¼ or even gr. ½ in an adult. This has been for many years the routine treatment in my wards, and I consider the idea that morphia should not be given to children under these circumstances to be entirely without foundation. If shock is severe immersion in a warm bath brings great relief, especially in the case of a child; the water should be rendered slightly alkaline by the addition of a handful of sodium carbonate in the form of bath salts or washing soda. No attempt should be made to remove the clothes, which can later on be cut off in the bath. A hot rectal saline infusion containing brandy may be given with great advantage.

Local Applications other than Paraffin Wax.

The essentials of a satisfactory local application are that it should be protective, painless, easily obtained, easily changed, and if possible mildly antiseptic.

Small burns, where the skin is not broken, may be dressed with gauze or other soft material soaked in a 10 per cent. solution of carbonate of soda (washing soda); a compress so made will give considerable relief to the pain, which is often especially severe in those parts which show only an erythema. Where the skin is broken a weaker solution should be used. In a limb Bier's method of passive congestion applied by means of a thin rubber bandage may give great relief, the bandage being applied high up the limb and with only just enough tension to obstruct the veins. Later on an ointment composed of equal parts of zinc ointment and castor oil may be used.

For *larger burns* it may first be necessary to clean up the surface, and this must be done under a general anaesthetic. But even under anaesthesia the procedure must be carried out with the utmost gentleness, and it is far better to leave the surface as it is than by rough handling to increase shock and destroy tissues which might otherwise survive. So far as is possible, the whole surface should be thoroughly cleansed with soap and water and then with 1/1000 perchloride of mercury, which is finally washed off with warm sterile water. The perchloride forms a coagulated layer on the raw surface and to some extent inhibits pain. Carbolic must not be used as it is too readily absorbed. Loose skin should be cut away, but blisters should only be punctured and the cuticle left for protection.

In my opinion, the best permanent dressing for the larger burns is paraffin wax, which will be described later. If this is not available; wet dressings may be used soaked in calamine lotion, or lead lotion to which 30 per cent. of alcohol may be added; or the area may be covered with strips of lint soaked in parolein or covered with the castor oil and zinc ointment already mentioned, a method especially applicable

to burns of the face. Moist dressings should be removed when necessary by immersion.

If the limb, or indeed the patient, can be kept continuously in a *warm alkaline bath*, nothing else can compare with this for comfort and rapidity of healing. It is not very difficult to keep children immersed in a bath, at least during the day, and in extensive burns of the body it is well worth while. As the patient floats in the water the injured surfaces are saved from all contact, perfect drainage is established, local hyperæmia is induced, the body heat is preserved, there are no dressings, and there is no pain. If an air ring of suitable size can be obtained and slipped round the body under the arms it furnishes an excellent means of support.

Picric acid has been very largely used and recommended as a dressing, but the danger of poisoning even with weak solutions is so considerable that we have given up its use. Picric acid in itself possesses only very weak powers as a disinfectant, and a weak solution of iodine would be far more potent if any such action is required. To some individuals picric acid is intensely toxic, its mere application to the uninjured skin producing serious results.

Paraffin Wax.

Of all local dressings paraffin wax, when it can be applied, is by far the best. It must melt at about 50° C., and it may usefully be combined with mild antiseptics. Of the many compounds on the market the original ambrine is as good as any. The following was widely used during the war as No. 7 paraffin: resorcin, 1 part; eucalyptus oil, 2 parts; olive oil, 5 parts; soft paraffin, 25 parts; hard paraffin, 67 parts. This should melt at 48° C. and will be found very satisfactory. It should be melted over a water bath and may be applied with a soft brush or with a spray. The burnt area should first be cleaned and dried, best of all with a stream of warm air. It is then covered with a layer of the wax, over which a very thin film of cotton-wool is applied. This in turn is covered with wax, so that the whole is converted into a thin protective shell, which does not adhere to the raw areas. Any discharge can readily break its way through cracks in the wax envelope. The whole is surrounded by a bulky layer of wool. Simple though it is, the method requires a certain degree of skill, and unless a special appliance is used it is not very easy to apply the wax at just the right temperature. I recently devised the following method which will be found to have several advantages. Strips of ribbon gauze, of narrow bandage, or of thin soft paper about an inch wide and 12 inches long are prepared. Holding a strip by its two ends it is run through the melted wax. The strip is now held for an instant over the area to be covered, until the edges are seen to whiten, when it is at exactly the correct temperature and is immediately applied around the limb or over the area. The strips are applied to the limb in series, exactly as if it were being strapped. They furnish complete protection and afford considerable support. By perforating the strips, or by leaving narrow gaps, room can be allowed for the escape of discharge. The burning of the patient with hot wax is absolutely impossible. One great advantage of a wax dressing is the time for which it may be left undisturbed. In many cases it may be left in place for a week, and at the end of that time it can be changed with great facility, for it will not adhere either to skin or to granulations. If the wound is very dirty, the wax dressing may be changed every day with very little inconvenience to the patient, the exposed surface being cleansed with peroxide of hydrogen and dried before a fresh layer of wax is applied.

Avoidance of Exposure.

Whatever method of dressing is adopted it is most essential that bandages should be applied very loosely. There may be considerable swelling of a burnt limb, and in any case any pressure on a burnt area is intolerable. It has been well said that in these

cases a neat bandage is the sign of a bad surgeon. It is equally important that in extensive burns no attempt should be made to change the whole dressing on one occasion, and the utmost care must be taken to reduce exposure to the absolute minimum in doing what dressing may be necessary. To expose the whole of a large burnt area on the body at one time is not merely bad surgery. It is criminal.

Prevention of Deformity from Contractures.

In certain areas great care is required to prevent subsequent deformity from contractures. This is especially the case in the neck, in the neighbourhood of joints, on the palmar surface of the wrist and hand, and in the calf. Such support must be provided as will keep the burnt area extended, and in some cases it may be better to fix the parts in a plaster case with an opening over the denuded area. When the skin all round the joint has been destroyed the position must be varied from time to time so as to maintain a full range of movement in all directions. Unless these precautions are taken contractures will form which are exceedingly difficult to correct. During the second week sloughs will separate and the area will commence to granulate. In this stage a peroxide spray is invaluable in assisting the separation of sloughs, washing away discharge, and combating sepsis. An occasional boric fomentation may help to clear things up. As the granulations become cleaner a compress of lint soaked in equal parts of red lotion and glycerine will be found to check exuberant granulations and to stimulate epithelial growth. The lint should be cut exactly to fit the granulating area, and it should be covered with a layer of rubber tissue or oiled silk cut a little smaller than itself so as to allow free escape to any discharge. The whole may be covered with a gauze dressing.

Grafts.—As soon as clean granulations have formed they should be covered with Thiersch grafts, as only by the provision of an epithelial covering can contractures be permanently prevented. The grafts will be more certain to take if gentle pressure can be applied to their surface, and for this we have found tinsel dress trimming most effective. It is a very fine elastic wire gauze, sold in large sheets and quite inexpensive. It is wrapped round the limb as a sleeve, which is stitched up along the side of the limb opposite to the grafts. Over it a dressing of gauze soaked in equal parts of red lotion and glycerine may be applied. After ten days the tinsel is removed, bringing with it a layer of dead cuticle, but leaving firm and healthy grafts behind, which will rapidly spread to cover the whole area.

Conclusion.

The successful treatment of a severe burn demands a degree of individual attention and of unremitting vigilance not always realised. In this way alone can severe contractures and terrible disfigurements be avoided, but the fact that they can be so avoided is a full recompense for the labour involved. Much can be done by massage, by ionisation, by very cautious X ray therapy to soften and remove scar tissue, but in preventing or at least limiting the formation of these scars the surgeon who first treats the case has an opportunity which will never recur.

London Hospital.

Special Articles.

A VISIT TO CULION LEPROY COLONY, PHILIPPINE ISLANDS.

BY A. R. J. DOUGLAS, M.D., B.S. LOND.,
F.R.C.S. ENG.,
CHIEF MEDICAL OFFICER, BURMA RAILWAYS, RANGOON.

I.

OWING to the formation of the British Empire Leprosy Relief Association with Sir Leonard Rogers as medical secretary, and the prospect of funds being available for a considerable expansion of the present treatment of leprosy in India and Burma, the writer of this article, who has been on the committee of the Rangoon Leprosy Asylum for nearly 20 years, decided to visit the Philippine Islands, where the Government are carrying on by far the largest work on the segregation and treatment of leprosy in the world at a cost of over £100,000 per annum. The following brief account is intended to draw the attention of those interested in leprosy to the very large and valuable scientific work being carried on there. No claim is made to any originality, the writer having endeavoured by making use of articles published and unpublished, freely placed at his disposal, to present the methods being carried out and the views held by the medical staff.

*The Culion Leprosy Colony.*¹

The space at my disposal does not allow me to deal with the questions of segregation and treatment in the way that they require. The Culion Leprosy Colony is an interesting institution, and in many respects unique. For the study of leprosy and its treatment it offers the most unusual opportunities. The largest well-organised leprosarium in the world, it contains in large numbers all types of the disease, and all degrees of advancement, except, of course, the earliest. The inmates are fairly amenable to reason, and little difficulty is experienced in obtaining adequate clinical material for any work desired. In spite of these facts the colony has not in the 17 years of its existence become widely known, and it is seldom referred to when leprosy work is discussed. This is undoubtedly due to the fact that until very recently it has served chiefly as an isolation colony.

With the access of interest in the treatment of this disease resulting from the reports of Rogers and co-workers in India, and, subsequently, those of Hollman and Dean and other Hawaiian workers, the desirability of extending modern treatment to the Culion inmates and of utilising the material for study was brought to the realisation of the authorities, and in 1921 provision was secured for starting such work on a small scale. The very keen and active interest of Governor-General Wood resulted early in 1922, a few months after its inauguration, in the expansion of this work to a more adequate scope. The establishment of a colony for the systematic segregation of lepers was started in 1901, and eventually Culion, on account of its water-supply and other advantages, was selected. Construction work at the site finally selected did not commence until 1905, a delay in part due, it is said, to conflicting opinions as to whether segregation would exterminate the disease. In 1906 about 500 lepers were transferred to the island.

The Present Colony.—A brief statement of the general features is necessary for any understanding of the conditions under which the work is being carried on. Culion Island is very irregular, measuring roughly 11½ miles from north to south, and 19 miles

ROYAL SOCIETY OF ARTS.—Among the meetings of the society to be held between January and March, in John-street, Adelphi, London, W.C., the following should prove of interest to the medical profession: Mr. V. E. Pullen, Director of the Radiological Research Department, Woolwich, will deliver three Cantor Lectures entitled "Radiological Research, a History," on Mondays, Jan. 19th and 26th, and Feb. 2nd, at 8 P.M. Dr. J. A. Owens, Superintendent of the Advisory Committee on Atmospheric Pollution, Air Ministry, will speak on Modern Atmospheric Conditions, on Wednesday, Feb. 18th, at 8 P.M.

¹ H. W. Wade and Jose Avellana Basa: Amer. Jour. Trop. Med., vol. iii., No. 5.

in its longest diameter. It has a total area of 15,059 miles, and lies about 200 miles to the south and west of Manila. The colony is everywhere surrounded by vistas of unusual beauty. The conditions of climate are very much the same as in Rangoon—that is to say, there is a rainfall of about 100 inches during the rains, which last four or five months. The temperature rises up to about 98° F. in the hottest time of the year. The colony is for the most part a nipa-roofed Philippine town of 5000 inhabitants, most orderly and clean, and with its water system, electric light, and ice plants. The institution comprises the non-leper staff headquarters, Balala, and the colony proper, some 600 yards away. The total area covered by the colony proper is estimated to be about 40 acres, and on this there are over 600 houses of lepers, and all of the Government buildings. The

low infectiousness, and compulsory segregation is not used in dealing with other diseases of comparable type. Yet the right of the State to apply this method is maintained. That it is justified in doing so is held in view of the general attitude of the public, which is caused largely by erroneous ideas of its infectiousness, its relative incurability (at least by the older methods), and the peculiarly repulsive nature of the lesions in the advanced stages. It is further justified because segregation is the only known practicable method of control in endemic regions, and because of the probable feasibility of eradicating it entirely by this method.

Method of Segregation.—It is overwhelmingly the opinion that in a country where the disease does not tend to become endemic rigorous segregation is not necessary. Norway's system of segregation, instituted

FIG. 1.—Panorama showing view of part of the leper colony.

administrative centre of the colony is Colony Hall, with the court-house of the chief of the colony and the Government store and colony post-office on the ground floor. The present chief of the colony is Dr. Jose Avellana Basa, who carries on the government of this fair-sized town, in part through and with the aid of the Advisory Board, an elective body of which he is *ex officio* the head.

The staffs of the general kitchen, the Government store, the colony branch of the post-office, the public works department, the sanitary department, the court, the land, and the orchestra are all lepers. Most of the routine nursing and all of the service work of the hospitals and clerics is done by leper employees. The spiritual welfare is largely in the hands of two priests. The Protestant inmates, who are in a minority, are aided by a missionary and his wife. This work is supported largely by the American Mission to Lepers. For the amusement of the inmates some little provision is made. Cinematograph shows are given at intervals; a string orchestra of lepers are paid monthly wages to play in the main plaza once a week; cock-fighting, a national sport, is permitted on Sundays and holidays, and at intervals the lepers stage fairly successful performances which appear to be much appreciated. For the most part the inmates lead very quiet, uneventful lives, finding such entertainment as they may in very little things.

*Segregation.*²

The question of segregation is a most difficult one, and to this day the most diverse and strongest views are held by scientific men who have closely studied the question personally. Leprosy is admittedly of

by Hanson, in which some cases, particularly of the cutaneous type, are kept in asylum, while others, chiefly of the neural type, are allowed to live under specified conditions at home, has apparently proved successful, but to assert that the Norwegian system would be effective in a radically different environment would be an inaccurate assumption. It is very likely that conditions, such as mode of living, personal hygiene and general sanitation, economic status, nutrition, and perhaps even race, and particularly climatic conditions, are determining factors of the activity of the disease in a country. It is open to some doubt whether the Norwegian system would be effective in Hawaii, the Philippines, and many other places. This view is endorsed by Sir L. Rogers.³

For such regions compulsory segregation in special institutions is probably the only practicable method. If there is created an antagonistic feeling among the people, lepers will hide as long as possible and so perpetuate the disease.

Albert⁴ believes that the Culion figures showed compulsory segregation to have failed in the Philippines, but his figures do not warrant the final conclusion drawn. Heiser estimates that before segregation, over a thousand new cases occurred annually, practically twice as many as the average for the past few years; whether the admissions will decline during the next 10 years or not, it is certain the results have been disappointing to those who expected a rapid diminution or total discontinuance of new cases. It was believed that after a district was once freed of known lepers few cases should occur thereafter. It is said that at the outset of the campaign

² An unpublished article on Leper Segregation. By H. W. Wade, M.D., Culion.

³ L. Rogers: Trans. Roy. Soc. Trop. Med. and Hyg., 1923, xvi., 440.

⁴ J. Albert: Jour. P.I. Med. Assoc., 1921, i., 133.

10 years was estimated to be sufficient to suppress the disease, and this statement has now sometimes been quoted as an argument that the system followed has failed. If there is no reservoir of infection other than human cases, it is obvious that thorough segregation will eliminate the disease.

It is 18 years since active work was begun at Culion, and certainly 10 or 12 since all previously existing cases known to the authorities were removed from most districts. It would appear that there has been a sufficient residuum of unsegregated cases to perpetuate the disease. This could hardly be otherwise.

As regards segregation for leprosy, the attitude of the people is usually not complacent, and cases must be numerous to make their isolation be considered impracticable, though in heavily infected countries like India it will undoubtedly be necessary to depend largely on education to limit the disease, as in the case of tuberculosis. Total suppression of the disease by segregation is believed to be possible, though our ideas as to the conditions that will make thorough segregation possible are being modified.

The method of transmission is unknown, but the consensus of opinion is that it is due to intimate personal contact with a leper. The nature of its ravages is a most potent factor in the general attitude. Segregation makes it possible to apply intensive modern treatment, but it is difficult to establish the right of the State to compel people to take prescribed medicines against their wills; even in leper asylums the consent and co-operation of the inmates are necessary. One important justification for segregation, though it does not appeal to the average leper, is the fact that it furnishes the best opportunity for research on the disease and its treatment.

Segregation in the Philippines.—This was one of the things which attracted the writer to visit the Philippines, and he cannot admire enough this gigantic and costly experiment. The position of affairs appears to be very much the same as in Hawaii in its earlier days. Owing to the fear of being sent to Culion there are probably a large number of unsegregated cases in the Philippines. The writer has been told by one recognised authority that he believes the number of lepers in the Philippines to be at least 10,000. Only about 6000 of these are segregated, 5300 at Culion. Recently, with the success of the new treatment, a number of volunteers have appeared, but many only on condition they should not be sent to Culion. A strong attempt is being made by means of statistics to show that segregation at Culion has failed, and to substitute a system of smaller leprosarías about the Archipelago. In support of this is Dr. Wade's view that intensive treatment is better carried out in a treatment station (asylum), where patients can be kept under closer observation than in a colony. It seems too early yet to lay much stress on statistics. Probably the figures do not indicate any definite reduction of leprosy in the Philippines.

As Dr. Wade says in his unpublished paper quoted above:—

"Conditions of segregation must be such as to cause the leper to be willing to undergo it for the chance of being cured. Segregation to be effective must be accomplished by attraction, not by compulsion alone. . . . The antagonists of Culion believe that the principal drawback is that it is in an isolated island, very difficult of access to friends of the inmates, and with inadequate provision for bringing visitors. To the Filipino the attraction of home and the family circle is very strong. On the whole the sorrow of separation is, perhaps, a greater deterrent than fear of the colony. If, therefore, several properly organised colonies were established, so situated that the inmates could be visited by their friends, the difficulties would be very much diminished."

In the sequel the question of treatment at Culion Leper Colony will be dealt with.

Under this heading will be included accounts of (1) the chemical section, (2) the pathological section, and (3) the actual treatment as carried out in the clinics and hospital wards.

NON-PAYING BEDS AT THE RADIUM INSTITUTE.

THE technique of radium therapy has altered considerably since the days when the metal or its salts were first applied externally to new growths in the attempt to destroy them without damage to normal tissue. In order to carry out the modern methods of burying in the growth tubes of radium, in the form of headless nails tethered by aseptic thread, the co-operation of the surgeon must be enlisted. More elaborate technique has brought with it the need also of operating theatres and of beds in establishments where radium therapy is practised.

The Radium Institute at Riding House-street, Portland-place, London, W. 1, has gradually expanded to three times its original size during the 14 years of its existence; for 12 of those years out-patients alone were received, but it became clear a few years ago that beds were needed, and in October, 1922, seven comfortable rooms were set aside for private patients, together with an operating theatre, anaesthetising and sterilising rooms. The patients occupying these rooms pay a nursing-home charge of £1 11s. 6d. a night in addition to the consultation and treatment fee; their stay varies from one or two nights to about a week. These beds did not, however, meet the needs of necessitous patients, and arrangements have now been made to accommodate three men and four women in non-paying wards divided into cubicles. Adjoining these wards are a special operating theatre, a service kitchen and pantry, bathroom and lavatories. The plan (see figure) shows the arrangement whereby

The new beds for necessitous patients. The room designated "examination room" on the plan has been equipped as an operating theatre, and the "private ward" serves as a duty room.

privacy has been secured without the use of screens, but it can hardly convey the pleasant and cheerful outlook in the cubicles as well as in the private rooms.

No charge is to be made to necessitous patients for treatment, operation and nursing, but patients will be expected, when possible, to contribute to the actual cost of their maintenance whilst in the Radium Institute. The regulations laid down by the governing body of the Institute provide that no patient shall be received for treatment except with the knowledge and consent of his or her medical adviser, who is requested to fill in and sign the prescribed form of certificate. The particulars of the patient's case are then considered by the medical staff, and if the case appear to be a suitable one for treatment, a dated admission order is sent to the patient. No patient can be admitted unless these formalities are complied with.

The Radium Institute was founded, equipped, and endowed by the late Sir Ernest Cassel and by Lord Iveagh, who is now its President. The executive committee consists of Sir Anthony A. Bowlby, the Chairman, Lord Rayleigh, F.R.S., Sir Felix Cassel, Mr. Walter Guinness, Sir George Blacker, Sir William H. Bragg, F.R.S., Sir Humphry D. Rolleston, and Sir

Joseph J. Thomson, F.R.S. The honorary consulting staff includes Dr. Herbert French, Dr. Cuthbert Lockyer, Prof. C. A. Pannett, Dr. J. H. Sequeira, Dr. Herbert J. Shirley, Mr. W. T. Holmes Spicer, Mr. Herbert Tilley, and Sir J. W. Thomson-Walker. Mr. W. Lester S. Alton, F.I.C., is director of the chemico-physical laboratory, and Dr. J. C. Mottram of the pathological research laboratory. The Institute possesses 6 g. of radium bromide and the latest form of emanation plant; examination rooms, X ray room (for diagnosis only), photographic studio, chemical, physical, and pathological research laboratories, carpenter's and engineer's shops, are all well equipped, and the rooms in which out-patient treatment is given are as warm and comfortable as the bedrooms. Indeed, throughout the Institute it is obvious that the convenience of the patient is the first consideration. Every patient before treatment is seen by Mr. Hayward Pinch, the medical superintendent, or one of his colleagues, Dr. Philip Gosse and Dr. Oskar Teichman, but this does not entail hours of dreary waiting, since all interviews and all treatments are by appointment. Since patients with operable tumours are strongly urged to consult surgeons, it follows that many of the sufferers from malignant disease who are accepted for treatment are in an advanced stage. Patients afflicted either with cancer or with unsightly if benign lesions, such as keloid, often suffer much from causes only indirectly connected with their pathological condition unless very tactfully handled. In order to secure the most judicious nursing no probationers are employed. The 14 nurses, including four men nurses, are all fully trained, and since a large proportion of the cases treated are gynaecological, a C.M.B. certificate is required of the women nurses. Practitioners who have not had the privilege of going round the Institute may safely reassure any patients who show reluctance to expose themselves to treatment by new persons in a strange place, for the place is home-like and the people are kind as well as skilful. Since the opening of this Institute some 10,200 patients have been treated within its walls, and 4500 have been treated at various hospitals, infirmaries, and nursing homes in all parts of the United Kingdom with emanation apparatus, supplied with the fullest instructions as to technique and exposures, to the surgeons or practitioners in charge of these cases.

We congratulate the Institute on its new enterprise and rejoice that whatever benefits radium can confer in prolongation of life and alleviation of symptoms may now be available for a larger number of patients.

TESTIMONIAL TO PROF. RUTHERFORD MORISON.

WE are glad to announce that a movement has been started among members of the medical profession in the north of England to commemorate the work of Emeritus Professor Rutherford Morison, of Newcastle, one of the most active and original leaders of surgical thought of our time, at present consulting surgeon to the Royal Victoria Hospital in that city. On Dec. 16th a largely attended meeting representative of all branches of the medical profession was held at Newcastle, at which it was unanimously decided to issue an appeal to the profession for subscriptions to present Prof. Morison with his portrait in oils, and, after defraying the cost of the portrait, to devote the balance either to the formation of a medical library fund or the establishment of a scholarship or a fellowship in research, or such other similar objects as Prof. Morison approves.

James Rutherford Morison, a son of John Morison, M.D., was born in Hutton Henry, County Durham, in 1853. He received his early education privately and began his medical studies in Birmingham, later proceeding to Edinburgh and Vienna. In 1874 he became L.R.C.S. Edin. and the following year graduated M.B. at the University. In 1879 he gained

the Edinburgh fellowship of surgery, and in 1890 the F.R.C.S. Eng. He began his professional life as house surgeon at Edinburgh Royal Infirmary and resident surgeon at the Cowgate Dispensary; then returning to England he settled in Newcastle, where he was appointed assistant surgeon to the Newcastle Royal Infirmary. From that auspicious beginning his work as a surgeon has grown. On the academic side he became lecturer on surgery at Durham University, and having filled the professorial chair for many years, now holds the title of emeritus professor. He is also examiner in surgery to the Universities of Liverpool and Birmingham. An hon. staff surgeon to the R.N. Reserve before the late war, he was appointed senior surgeon to the Northumberland War Hospital during hostilities and later senior surgeon to the War Pensions Hospital. His contribution to war surgery, with which his name will always be associated, was the treatment of war wounds by iodoform, bismuth, and paraffin paste—bipp—a method which achieved remarkable success.

Prof. Morison has made many valuable contributions to surgical literature both in standard medical text-books and in the columns of medical journals. His name is a familiar one on THE LANCET files. He published an introduction to surgery in 1910, an extremely suggestive work designed to supplement the standard text-books, and in 1916 appeared in collected form his "Surgical Contributions from 1881 to 1916." In the large number of papers collected into two volumes we find everywhere the same acute recognition of the essential points, the same accurate appreciation of the value of theories and methods which have been recognised in Prof. Morison by all who have had the privilege of knowing him. Prof. Morison has been honoured by his alma mater with the LL.D. Edin., and Durham University has awarded him both an honorary M.A. and the D.C.L.

Formation of a General Committee.

A general committee has been formed to further the projected testimonial, and an executive committee has been appointed also. The latter consists of the following members of the medical profession:—

Prof. H. Brunton Angus (Chairman), Newcastle; Dr. J. Anderson, Blyth; Dr. P. V. Anderson, Bishop Auckland; Dr. J. S. Arkle, Newcastle; Dr. R. A. Bolam, Newcastle; Dr. T. L. Bunting, Newcastle; Dr. J. Charles, Consett; Dr. H. B. Densham, Stockton; Dr. H. Dickie, Morpeth; Mr. W. S. Dickie, Middlesbrough; Dr. R. H. Lix, Sunderland; Dr. J. Don, Newcastle; Dr. W. Fairclough, Hexham; Dr. F. T. T. Hare, Durham; Dr. G. R. Harland, South Shields; Dr. J. Hudson, Newcastle; Dr. W. Mackenzie, Gosforth; Mr. A. M. Martin, Newcastle; Dr. Farquhar Murray, Newcastle; Dr. O. W. Ogden, Newcastle; Dr. H. C. Pearson, Darlington; Dr. Scott Purves, Alnwick; Dr. R. H. Smallwood, Gateshead; Mr. G. Grey Turner, Newcastle; Dr. Eleanor Walkinshaw-Osselton, Newcastle; Dr. J. B. Williamson, North Shields.

The following subscriptions have been received or promised to date. It is hoped to raise a sum of at least £2000.

£52 10s.—Mr. Hamilton Drummond, Newcastle; Mr. G. G. Turner, Newcastle; Mr. R. J. Willan, Newcastle.
 £25.—Mr. A. M. Martin, Newcastle; Prof. H. Brunton Angus, Newcastle; Dr. J. W. Smith, Ryton.
 £21.—Dr. R. A. Bolam, Newcastle; Dr. James Don, Newcastle; Dr. James Hudson, Newcastle; Dr. D. F. Todd, Sunderland.
 £15 15s.—Dr. J. S. McCracken, Newcastle.
 £10 10s.—Dr. Baigent, Northallerton; Dr. R. H. Dix, Sunderland; Dr. Forsyth, Cramlington; Dr. Fox, South Moor; Dr. Giffon, North Shields; Mr. N. Maclay, Newcastle; Dr. W. Mackenzie, Gosforth; Dr. Scott Purves, Alnwick; Dr. H. Smith, Durham.
 £10.—Dr. J. T. Dunlop, Newcastle; Dr. A. Smith, Ryton.
 £5 5s.—Dr. W. Fairclough, Hexham; Dr. H. E. Gamlen, Newcastle; Dr. T. W. Hay, Newcastle; Dr. D. W. Inglis, Hebburn; Dr. J. F. Longbotham, Middlesbrough; Dr. Moyes, Broomhill; Dr. Gavin Muir, Newcastle; Dr. James McDonald, Belford; Dr. Macleod, Alnwick; Dr. Eleanor Walkinshaw-Osselton, Newcastle; Dr. H. Carden Pearson, Darlington; Dr. E. F. Pratt, London; Dr. Stanley Robson, Rowland's Gill; Dr. J. B. Williamson, North Shields; Dr. Stanley Worthington, Newcastle.
 £5.—Dr. H. Dickie, Morpeth; Mr. C. D'O. Grange, Harrogate; Mr. A. S. Percival, Newcastle.
 £3 3s.—Dr. Monica Bell, Humshaugh; Dr. J. Galloway, Low Fell; Dr. G. H. Harbottle, Gosforth; Dr. W. Jaques, Washington; Dr. E. E. Norman, Hebburn; Dr. Z. Ross, Sunderland; Dr. T. L. Wormald, Darlington.
 £2 2s.—Dr. J. Chalmers, Sunderland; Dr. Densham, Stockton; Dr. Hubbersty, Sunderland; Dr. W. Robinson, Sunderland; Dr. W. J. Ruddock, Newcastle; Dr. Ross, Stockton.

£1 ls.—Dr. Bishop, Wylam; Dr. A. Brownlie, Redcar; Dr. J. Brydon, Stockton-on-Tees; Dr. J. Crombie, Castle Douglas; Dr. Devey, Richmond; Dr. Hall, Stockton; Dr. Bruce Low, Sunderland; Dr. S. Lyle, Stockton; Dr. C. V. Miller, Stockton; Dr. A. T. Thompson, Darlington; Dr. L. M. Weeks, Newcastle; Dr. Ethel Williams, Newcastle.

10s. 6d.—Dr. G. Irving, Stockton; Dr. T. Kirk, Stockton; Dr. Manners, Stockton.

INFECTIOUS DISEASES ABROAD.

Encephalitis Lethargica in Europe during 1924.—In view of the high incidence of encephalitis lethargica in England and Wales during 1924—namely, 5017 cases as compared with 1023 in 1923—it is surprising that there was little change in the annual incidence in other European countries. Up to the dates in 1924 for which statistics are available from the 11 European countries in which the disease is notifiable, Italy is the only country where the number of reported cases exceeded those of the previous year. The following statement gives the available figures of cases in those countries during the two years. The figures of deaths are available from only one or two countries so that at present it is not possible to compare fatality rates. In England and Wales 26 per cent. of the cases were fatal as compared with 33 per cent. in 1923.

	1923	1924
	Cases.	Cases.
Norway	10	10 (to Nov. 30th).
Sweden	336	283 (to Nov. 30th).
Finland	83	35 (to Nov. 30th).
Denmark	88	77 (to Oct. 31st).
Belgium	27	20 (to Dec. 10th).
Switzerland ..	203	86 (to Dec. 20th).
Italy	277	591 (to Nov. 30th).
Czecho-Slovakia	366	82 (to Sept. 30th).
Lithuania ..	86	7 (to Nov. 30th).
Latvia	—	3 (to Nov. 30th).
Estonia	12	3 (to Oct. 31st).
Russia	899	810 (to June).

Plague in the Azores.—The Portuguese islands of the Azores, in the mid-Atlantic about 700 miles from the coast of Portugal and about 1500 from Liverpool, lie on the natural highway from Europe to America and on other great trade routes. From time to time since 1910 outbreaks of plague have been reported in four of the nine islands which constitute the group, but, except for approximate numbers of cases and deaths, little or no information about the outbreaks is available. The following statement gives the recorded figures in each of the last five years:—

	1920	1921	1922	1923	1924
	C. D.	C. D.	C. D.	C. D.	C. D.
St. Michael Island ..	140 47	71 30	385 81	200 84	17 13
Pico Island	? 15	—	—	—	—
Fayal Island	—	1 —	? 5	3 —	—

C = Cases.

D = Deaths.

A characteristic feature of the outbreaks has been the predominance of cases of pneumonic type with a high fatality and spreading from person to person by direct contact. This happened with the outbreak in the Island of Pico in 1920, in regard to which it is said that the inhabitants of the island became so alarmed that they segregated the affected families in an area surrounded by a deep trench and sharp-pointed wooden stakes. The present outbreak at or near Ponta-Delgada, the chief town and port of the Island of St. Michael, and in neighbouring parishes, is chiefly of the same type, but there are also cases of bubonic type, particularly in the districts of Arrifes and Ribeira-Grande. It appears to be a recrudescence of a small outbreak of eight fatal cases which occurred in January of last year and in which the first case was described as being of bubonic type with secondary pneumonia.

¹ See THE LANCET, Jan. 3rd, 1925, p. 13.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Trinity College, Dublin.

Regius Prof. John Mallet Purser has made a gift of £10,000 to be administered for the benefit of the School of Physic and the Schools of Experimental and Natural Science by a committee consisting of the heads of three of the scientific departments of the College. The Board of Trinity College, in gratefully accepting his most generous donation, has expressed to Prof. Purser its desire that he should associate himself with the committee in the administration of his gift and Prof. Purser has consented to do so. Prof. Purser's connexion with the teaching staff of Trinity College dates from the year 1874, when he was appointed King's Professor of the Institutes of Medicine (Physiology and Histology) by the Royal College of Physicians. He held this professorship until his resignation in 1902. Probably no man exercised a greater influence over the minds of generations of students in the school than Prof. Purser during these 28 years. He was responsible for the teaching of physiology, and was, it is believed, the first man in Ireland to give formal lectures and conduct practical classes not only in histology, but also in modern pathology. During the years that he held the King's Professorship he acted as physician to Sir Patrick Dun's Hospital. In 1917 Prof. Purser was nominated by the University Council, and appointed by the Board of Trinity College, to the Regius Professorship of Medicine, a position which he still holds. This appointment has given the greatest pleasure and satisfaction to his many former pupils. His numerous friends, not only in Dublin but all over the world, will hope that Prof. Purser for many years to come will continue to hold this high position and preside over the School of Physic in the University to whose service he has devoted his life.

Royal College of Physicians of Ireland.

At their December meeting, the President and Fellows of the Royal College of Physicians of Ireland unanimously elected Sir Humphry D. Rolleston, President of the Royal College of Physicians of London, to the Honorary Fellowship of the College. Sir Humphry Rolleston has arranged to visit Dublin early in February, and the Honorary Fellowship will be conferred on him in the College Hall on Feb. 7th. He will deliver an address on Personal Links Between the Royal Colleges of Physicians of London and of Ireland. In the evening he will be the guest of the President and Fellows at the term dinner of the College.

The Bad Weather and the Poor.

The peasantry of South and South-Western Ireland is suffering considerable hardship as the result of the recent bad weather. It has been impossible to cut and dry peats, and the prospect in consequence for the ill days that are yet to come is bleak. With the object of alleviating distress in the poorest parts of the country, a meeting is being held, under the Lady Dudley Nursing Scheme, in the Engineers' Hall, Dublin, on Friday, Jan. 16th, when it is hoped to outline some helpful plan. Lady Mayo will preside, and the Governor of the Free State and several other well-known speakers will address the meeting.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

What Is a Fresh Egg?

THIS perennial question was again raised last month in the French law-courts, and the prosecution conducted in the Tenth Chambre du Tribunal Correctionnel de la Seine of certain vendors who had passed off preserved eggs as fresh, has clarified the situation. At any rate, grocers in France now know exactly where they stand,

and what risks they run of fine and even imprisonment if they convey to their customers the impression that their eggs are straight from the hen and not straight from cold storage. In the course of this prosecution much ingenuity was shown in the definition of the term "a fresh egg." It was urged, presumably on behalf of the persons prosecuted, that an egg should be regarded as fresh when it showed no changes on transillumination, and when it could be used for all the culinary purposes for which a fresh-laid egg is fitted. This definition was criticised as being altogether too elastic: as leaving the door open to abuses, and as giving a sort of passport to the egg which, after a five or six months' sojourn in cold storage, is susceptible to rapid deterioration on its emergence therefrom. Incidentally, it should be noted that, of the million odd "fresh" eggs consumed daily in Paris, only a negligible 500 or so are laid on the same day or the day before. The definition of a fresh egg formally accepted by the Tenth Chamber was "that which has not been subjected to any process of conservation." Eggs for boiling—*les œufs coque*—must not, according to the ruling of this Court, be more than 15 days old in the summer or more than three weeks to a month in the winter. Fresh eggs—*les œufs frais*—are those which, though somewhat older, are still fit for cooking purposes without having undergone any process of conservation. Preserved eggs—*les œufs de conserve*—are those which, for a shorter or longer period, have been artificially prevented from undergoing spontaneous deterioration by being kept in storage. The persons prosecuted were condemned to 15 days' imprisonment in addition to a fine, and it is to be hoped that these disciplinary measures will prove a most effective mnemonic to traders who are apt to be forgetful of the birthdays of their wares.

The Episcopes.

In my last letter I referred to the use of the cinematograph in demonstrating vivisection experiments to students. Films, of course, can also be taken of surgical operations on the human body, and are instructive, but the new apparatus now in use of the St. Louis Hospital is likely to prove of much greater value. This is the episcopes, a sort of glorified epidiascope, by which the actual operation, at the time when it is being performed, is projected on to a screen in a room adjacent to the operating theatre. The part of the patient on which the surgeon is working is strongly illuminated with beams from electric light projectors, and, immediately above, but placed so as not to interfere with the surgeon, is a lens like that of a camera or magic lantern. The image is picked up, and the beam is deflected at right angles by a prism and passed through a tube to a lantern in an adjoining room where it is thrown on a screen. Students can follow every movement of the instruments guided by the surgeon's hands, and can take notes in comfort without any risk of distracting the doctors and nurses. But what is more important, next door in the operating room all is quietness and not a single unnecessary movement disturbs the air or the surgeon's sang-froid. The value of this apparatus lies in the fact that there can be no possibility of "faking" the picture, and the surgeon's mistakes are recorded along with his successes. Nevertheless, merely to watch the surgeon's manipulations is not enough. An operation theatre is a theatre in more senses than one, for in the actual presence of the living actors in the drama on the operation table there comes to the student a tenseness, a sense of responsibility that no amount of mere visual perception can ever quite replace.

Vivisection.

Reverting to the subject of vivisection, there has been a good deal of public feeling raised during the past year through the instrumentation of certain political journals with regard to animal experimentation in laboratories. In July of last year the Minister of Hygiene drew the attention of the Academy of Medicine to acts which he designated as being of useless cruelty, and he asked if it would not be

possible to limit the number of laboratories and to organise some supervision of the experiments. A commission, which included Prof. Balthazard, was appointed to look into the matter. Prof. Balthazard has now reported to the Academy of Medicine that useless cruelties are never practised in our laboratories. He also points out that vivisection at the present time in no way resembles what was practised under that name in the time of Claude Bernard. Nowadays experiments are conducted in exactly similar fashion to operations on human beings, and, further, we now possess anaesthetics which abolish pain but do not nullify scientific results. On the other hand, he states it is impossible to limit the number of laboratories authorised to carry out vivisection experiments, as such a limitation would be equivalent to granting a monopoly of biological discovery to certain institutions. As regards the control of vivisection, this is already in existence, as the laboratories are under the surveillance of the deans of the medical faculties and the directors of scientific institutions. Also, it would be intolerable to permit lay strangers to be present at and criticise operations. It is to be hoped that the conclusions expressed in this report will assure the Minister and the political press that there is no occasion for misplaced excitement.

BUDAPEST.

(FROM OUR OWN CORRESPONDENT.)

The Treatment of Scabies in Infants and Young Children.

Dr. Zoltán Barabás, director of the Children's Asylum in Gyula, Hungary, has used the following routine treatment in cases of scabies of infants and young children, and has had excellent results with it. The hair and nails are cut short. A warm bath is given in which the patient is immersed for some considerable time, his skin being abundantly soaped and rubbed with a soft brush, in order to remove the superficial pus-vesicles and crusts. It is advisable to add 1 per cent. lysol to the bath-water. After the bath the skin is well dried and one of the following ointments applied: Milk of sulphur, 15 g.; potassii carbonate, 10 g.; green soap, 5 g.; lard ad 100; or sulph. precipit., creta alba, oxide of zinc aa 12 g., vaseline ad 100. With infants under 6 months it is advisable to increase the quantity of the vehicle by one-third, as the ointment is likely to irritate the macerated skin. Inunctions are to be made on three to four successive days, once a day, if possible by daylight, to ensure visually that the whole body is anointed. The inunctions must be made energetically, each manipulation lasting from eight to ten minutes. Special attention must be paid to the head, ears, neck, and in general to all flexures. All pus blisters must be incised, and afterwards dressed with the above ointments.

Diet for Obstinate Constipation.

Dr. Sigmund Serb, lecturer on clinical medicine at the university, prescribes the following diet in cases of spastic constipation. Half an hour before breakfast: one tablespoonful of pure honey with three tablespoonfuls of warm water. At breakfast: besides common sugar, one teaspoonful of milk-sugar, along with plenty of butter, jam, and rye bread. Before noon: Raw and preserved fruits. Lunch: To be avoided are, kohlrabi, cabbage, radish, horse-radish, cucumber, onion, unsieved beans or peas, puddings prepared with yeast, green or over-mature cheeses. Recommended are: Carrots, and green vegetables other than the above, cooked with soup, plenty of vegetables and little meat, much salad and cooked fruits, soft cheese. Tea, as for breakfast. Dinner: Anything excepting the foods to be avoided, as enumerated above for lunch. Meat and eggs must be erased from the dinner bill-of-fare. Recommended are cooked or raw fruits, spinach, carrots, potatoes, asparagus, green beans, green peas, soft cheese, milk, yoghurt, gervais, light puddings, tarts, aspic jelly,

bacon, and as much butter as possible. In general, the keystone of this diet is the consumption of plenty of butter, at least 120-130 g. a day. Before going to bed 10-12 dried plums steamed in about 10 oz. of water to which is added one teaspoonful of milk-sugar, the whole to be passed on a sieve. Instead of white bread rye bread is always to be served. As for mineral waters, there are hundreds which are useful, provided that the carbonic acid is first driven out from them by warming the bottle.

Diathermy in the Treatment of Gonorrhœa of Women.

Dr. John Bársony, professor of obstetrics and gynaecology at the University of Budapest, writing on gonorrhœa of women, touches the question of the usefulness of diathermy in cases of exudates and pelvic cellulitis. He maintains that diathermy is a very useful auxiliary in the treatment of the gonorrhœal inflammations which sometimes defy all usual forms of therapeutics. Such are the cases where the uterus along with the tubes and the ovaries, and, chiefly, the posterior uterine ligaments are getting very tender. Such women are continually complaining of pains in the back and abdomen, and of general malaise; they envy all those who are healthy, and become embittered as to their fate. Particularly acute are these complaints during menstruation. This condition is usually termed post-gonorrhœal, but it is not. These women are still infected with gonococci, which are quiescent and are aroused periodically. In treating this condition diathermy is most effective. The heat applied in the pelvis, though not burning the tissues of the body, kills the gonococci. Improvement and even cure may be effected by a few sittings. Such cases should be sent by the practitioners to the institutions equipped with diathermy apparatus, while inflammatory swelling of the adnexa and exudates may be left under the care of the gynaecologist.

Post-Graduate Course on Dietetics.

The post-graduate courses held last year in Budapest have proved a great success. Foreigners came to attend them in unexpected numbers. The last course was held in December on the theoretical and practical study of X ray work. The first course for this year is now being held and deals with dietetics. The lectures are held in the clinics of Prof. Alexander Korányi. The course comprises theoretical lectures on the dietetics of different internal diseases, metabolism, with practical analyses, and practical exercises in the laboratory on the culinary art. The fees for the course and full board for foreigners in the guest house of the clinic amount to 50 American dollars. While such post-graduate courses are productive of good results, the great inrush of students to the medical faculty of Budapest is raising fears among medical men of the city that the profession will become overcrowded. The territory of Hungary is now only one-third the size it was before the war, yet the number of medical students at present matriculated in Budapest University is 2062. Even in pre-war days this number would have been regarded as excessive.

THE LATE DR. C. D. SHEPHERD.—Charles Dunbar Shepherd, M.R.C.S. Eng., senior consulting surgeon to the Wigan Infirmary, died at an advanced age on Jan. 8th at the house of his son at Ross-on-Wye. Dr. Shepherd for many years was a busy practitioner in the Wigan coalfield district, and was associated with the Royal Albert Edward Infirmary at Wigan ever since the institution was opened by the late King Edward, when Prince of Wales, 52 years ago. Prior to the building of the infirmary, Dr. Shepherd was for a number of years surgeon at the Wigan Dispensary. Forty years ago, owing to ill-health, he found it necessary to resign his position on the medical staff of the infirmary, and retired to Arnside where he resided for many years. On his retirement he was elected honorary consulting surgeon to the Wigan Infirmary, and at his death he was the senior consulting surgeon. Dr. Shepherd qualified in 1862 as M.R.C.S. and L.S.A., having pursued his medical studies at King's College, London, of which he was an Associate.

PATHOLOGICAL SOCIETY OF GREAT BRITAIN AND IRELAND.

A MEETING was held in the Thompson-Yates Laboratories of the University of Liverpool on Jan. 9th and 10th, Profs. E. E. Glynn and J. M. Beattie presiding.—W. Blair Bell (Liverpool) described the specific action of colloidal lead in causing necrosis of the fetal placenta and consequent abortion; the effective aborting dose is about one half of the fatal dose. Copper may cause abortion due to hæmorrhage and if sufficient is given to produce this result it is generally fatal. Thallium is very little and thorium not at all toxic in reasonable doses.—A. H. Miller (Midhurst) had treated tuberculous guinea-pigs with the esters and salts of some unsaturated fatty acids found useful in leprosy but without any good result. Some of the preparations were definitely poisonous, for example, the very unsaturated Japanese sardine oil.—G. Hadfield (Bristol) narrated a case where a tourniquet was by mistake left on the leg too long; the patient died several days later with symptoms compatible with secondary shock, and post mortem extensive necrosis of the leg muscles was found.—A. F. B. Shaw and R. P. Smith (Newcastle) described five cases of Riedel's chronic thyroiditis which produces singularly hard goitres, generally causing dyspnoea and often mistaken for sarcoma. There is diffuse lymphocyte infiltration with definite lymphoid follicles and much fibrosis; the destruction of the proper parenchyma varies in different cases and in different parts of the same gland. One case had Addison's disease and the suprarenals were found to be destroyed by the same process.—J. S. Dunn and N. A. Jones (Manchester) had studied the excretion of water and urea in experimental oxalate nephritis in relation to the accumulation of urea in the blood. The two largely run parallel, and the induction of polyuria by increasing the water intake raises the excretion of urea and may substantially lower its level in the blood. The same authors, with J. H. Dible and B. A. McSwiney, had failed to find any difference in blood circulation-rate in normal and nephritic kidneys.—F. S. Fowweather (Leeds) described a hypobromite method of determining blood-urea which was good enough for clinical purposes.—G. S. Williamson (London) described the finding of colloid droplets and degenerated cells in the ventricular fluid in encephalitis lethargica, and held that the primary change was an ependymal catarrh; the familiar perivascular cell aggregates are the consequence of the anatomy of the parts.—D. F. Cappell (Glasgow) described a case of liver-cell carcinoma with many secondary deposits in the lungs, heart, brain, &c., and numerous microscopic metastases in the spleen pulp.—M. J. Stewart and A. L. Taylor (Leeds) dealt with adenomyoma of the stomach, of which they had met with five cases, one an accidental autopsy finding and four removed by operation. The thickened plaques, one or two inches across, towards the pyloric end are composed of variable mixtures of Brunner's glands, more or less differentiated, pancreas, and smooth muscle, and the condition is to be regarded as a heterotopic malformation.—J. Davidson (Edinburgh) had produced a malignant tumour with widespread metastases in a rabbit by the subcutaneous inoculation of an ethereal solution of tar; the structure was indeterminate but was apparently sarcomatous.—W. A. Alexander (Edinburgh) described a typical sacrococcygeal chordoma in a man of 61, and specimens of the same tumour were shown by A. Young and R. Muir (Glasgow), and by A. Peyron and M. J. Stewart (Leeds).—W. A. Alexander also showed a sacrococcygeal tumour from an adult female which had the structure of a capillary carcinoma, recalling some papillary kidney tumours and also the choroid plexus; it was suggested that it was either an exceptionally uniform teratoma or came from the neurenteric canal.—H. W. Crowe and W. G. MacDonald (Harrogate), in an extensive series of

observations on the relation of staphylococci of the scalp to rheumatoid arthritis, had found that a special variety of coccus was regularly agglutinated by the serum of patients with that disease and not by normal sera.—C. C. Okell, T. Dalling, and L. Pugh (London) dealt with the frequency of leptospiral jaundice in dogs in England causing a disease known as "yellows" and often confused with distemper, and showed its specific identity with the spirochaetosis icterohæmorrhagica of men, rats, and experimental animals. Considering the widespread diffusion of the organism in rats and dogs the rarity of human infections is remarkable.—W. W. C. Topley, J. Ayrton, and E. R. Lewis (Manchester) had investigated the possible influence of bacteriophage on aertrycke infection in mice. Feeding lytic filtrates to carriers did not stop excretion of the bacilli. Feeding lytic filtrates with bacilli to normal mice did not prevent infection and the induction of the carrier state. Adding large quantities of lytic filtrates to the animals' water-supply made no difference to the progress of mouse epidemics. Feeding or vaccination with bacteriophage gives no protection against subsequent inoculation with bacilli. No evidence was, therefore, obtained that bacteriophage had any protective or curative value.—A. D. Gardner (Oxford) described his studies of the minute details of the mode of multiplication of the branched forms of paratyphoid cholera and other bacteria.—J. W. McLeod and J. Gordon (Leeds) said that bacteria do not produce glutathione, but its reduction by them to the stage, giving a nitro-prusside reaction, was a useful measure of their reducing power which the authors related to the capacity of different kinds to produce hydrogen peroxide.—J. W. McLeod and B. Wheatley (Leeds) described experiments showing that "peptone" contained substances inhibiting bacterial growth.—M. J. Stewart (Leeds) presented an interim report of the Status Lymphaticus Committee showing, as far as the number of cases investigated allowed, that really normal healthy young persons often had large thymuses and that the reality of status lymphaticus as a cause of unexplained deaths was highly problematical.—J. Cruickshank (Aberdeen) found that strongly alkaline emulsions of fæces gave pure cultures of *Streptococcus faecalis*, strongly acid emulsions gave *B. acidophilus*, and other streptococci, coli being in both cases completely suppressed. On subsequent culture the streptococci were not particularly resistant to acid and alkali.—A. E. Boycott and C. Price-Jones (London) had failed to get experimental evidence that muscular fatigue promoted infection of rats with Gaertner's bacillus or with tubercle bacilli; exhaustion is associated with a great fall in body temperature unless the external temperature is high.—A. T. Glenny (London) drew attention to the variability in the individual responses of animals to toxin injections, and urged caution in drawing conclusions from small numbers of experiments.—E. E. Glynn, R. E. Roberts, and P. Bigland (Liverpool), from a careful analysis of several hundred cases from the local venereal diseases clinic, had found that, when treatment by salvarsan and mercury had brought a Wassermann reaction to the negative, the further administration of mercury by the mouth and especially as grey oil by injection encouraged rather than prevented both Wassermann and clinical relapses. In discussing the possible explanations of this unexpected result they considered the production of mercury-resistant strains of the spirochæte and a general lowering of resistance by the mercury as the most likely factors.—E. E. Glynn and R. Jones (Liverpool), in studying the blood groups of 40 medical students by agglutination and absorption, had come across seven cases in which the cells or sera gave anomalous reactions.—In the demonstrations R. P. Smith (Newcastle) showed a large calcified deposit in the brain, probably a tuberculoma; J. M. Beattie (Liverpool) specimens of foot-and-mouth disease in rats, specimens of pneumonic and bubonic plague, and mesenteric gas cysts in a pig; A. H. Miller (Midhurst) a case of lymphosarcoma in a pig; H. Evans (Liverpool) specimens of leontiasis ossea and of hair balls; W. A.

Haig (Cardiff) a streptothrix; and G. S. Williamson and I. H. Pearse (London) the relation of lymphoid tissue to the primary lesion in gastric ulcer.

PEOPLE'S LEAGUE OF HEALTH: WORK OF THE CHILDREN'S COURTS.

A MEETING was recently convened at 12, Stratford-place, London, W., when certain members of the London County Council met unofficially members of the voluntary Advisory Council of the People's League of Health, and the magistrates sitting in the Juvenile Courts, who are advocating reforms in the working of the children's courts in this country. There were present: Mrs. Mathew, J.P., L.C.C., and Miss Adler, J.P., L.C.C., in an unofficial capacity; Dr. A. F. Tredgold, Dr. R. G. Rows, Dr. R. H. Cole, Dr. E. D. Macnamara, of the voluntary Advisory Council of the League; Mr. Clarke Hall, presiding magistrate, Shoreditch Children's Court; and Dr. F. C. Shrubbsall. Dr. Tredgold stated that the after-effects of encephalitis lethargica, accounting for much delinquency, were often not recognised in courts, and stressed the fact that this disease was increasing alarmingly. The speaker raised the question as to whether the L.C.C. should be responsible for setting up a special department for the proper investigation of delinquency in children under 16 years of age. Miss Adler pointed out that if a small number of magistrates were specifically appointed to try children's cases, more even treatment would result. The suggestion was made that provision might be made in the Children's Act for the appointment of such special magistrates. Dr. Macnamara suggested that an itinerant magistrate going from court to court would bring powerful influence to bear on the case being heard; while Dr. Rows instanced the practice in Boston, U.S.A., where a clinic is set up in connexion with these cases, and a visiting staff inspects the home of the children, and the magistrates in court have the benefit of this information. Dr. Shrubbsall stated that the Children's Act in Canada conferred greater powers on the magistrates than in England. The Advisory Council was of opinion (a) that Juvenile Courts should not be regarded as criminal courts, but as courts exercising Chancery jurisdiction, and that no child under 14 years of age should be "convicted," since such conviction involved a stigma upon the child in after life and might prevent his being received in one of the colonies. It was unfair that a child whose bad surroundings made it necessary to send him to an industrial school involved a "conviction." (b) That greater powers were needed by the President of a Children's Court with regard to custody—e.g., in arranging for the custody of children whose parents consented to such adjudication. (c) That a more satisfactory statistical basis was required, both to determine the child's immediate treatment and future work, and this could only be supplied by a physiological and psychological examination of all serious cases of delinquency. (d) That a special home should be established in this country, where medical observation of delinquent children could be systematically and fully made, for this alone would assist the magistrates in court to a complete understanding of the facts of each case before making his recommendation to the court. This was strongly endorsed by Mrs. Mathew. Miss Nethersole, honorary organiser of the League, congratulated those present on the unanimity of opinion that had been reached.

A series of nine lectures will be delivered at the Medical Society of London, 11, Chandos-street, Cavendish-square, W. 1, on What We Should Eat and Why. The first lecture will be given on Wednesday, Jan. 28th, at 6 P.M., by Dr. Leonard Hill, F.R.S., entitled the Nature and Purpose of Food. Tickets and further information can be obtained from Miss Nethersole, 12, Stratford-place, W. 1.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.—At the instance of the Board of Control, a special course in the study of malaria, both from the clinical and laboratory standpoints, is being arranged in February for medical superintendents of mental institutions, for guidance in the treatment of general paralysis of the insane by inoculation of malaria blood.

ROYAL COMMISSION ON NATIONAL HEALTH INSURANCE.—The twelfth meeting of the Commission was held at the Home Office, Whitehall, on Jan. 8th, Lord Lawrence of Kingsgate in the chair. The examination of Mr. Edwin Heather, representing the Independent Order of Oddfellows, Manchester Unity, was continued on the following subjects: Dental benefit, extension of medical benefit, the benefits of married women deposit contributors, exempt persons. Proof copies of the oral evidence given at the meetings of Dec. 11th, 18th, and 19th, 1924, are now on sale at H.M. Stationery Office.

Public Health Services.

THE APPLICATION OF APPROVED SOCIETY SURPLUSES.

In the face of the announcement that the surpluses at the second valuation of approved society funds are likely to reach the very large sum of £30,000,000, it really seems possible for a great advance to be made in the development of the service. At the last valuation there was an overwhelming desire to use the surplus of 17 millions for the main purpose of increasing the cash payments to members in sickness and disablement, but with a surplus of nearly double the amount the anxiety appears to be rather to limit the amount of additional cash benefits, to increase the provision of dental treatment (including dentures), and to extend medical benefit to include specialist and consultant services. It is even suggested that a portion of the surplus might be devoted to research work into the causes of cancer, neurasthenia, and arthritis—all prolific causes of sickness and disability constituting the greatest drain on the funds of the societies. Whatever is decided as to the disposition of the surplus, an attempt should be made on this occasion to establish additional benefits which shall be available to all insured persons, no matter in what society they have membership. While these funds are at present only applicable to certain purposes, the feeling is steadily growing that all the resources of the insurance scheme should be pooled so that a broad scheme of development may be set on foot as soon as the report of the Royal Commission is presented. Our immediate concern should be to convince the public that this development is following the right lines and that the expenditure involved is money well invested. We should be able to guarantee that the return is not only a sound financial investment, but also a much greater gain in the production of a healthy and happy community.

A COUNTY SPECIALIST SERVICE.

The first (and only) report of the Consultative Council on Medical and Allied Services gave as an illustration of a concerted scheme of services the actual example of Gloucestershire, "where the local authorities in the county and its towns, the hospital authorities, and all the doctors have agreed on a plan of services similar to that set forth in this report." We have just received, through Dr. J. Middleton Martin, a report of the Medical Services Committee of the Gloucestershire County Council, dated Dec. 1st, 1924. It seems clear from the figures given therein that the service at present deals mainly with child welfare and the treatment of school-children, though cases of venereal disease and tuberculosis also appear in the tables. The interest of the tables lies in the fact that during the quarter ending June 30th, 1924, specialist services were utilised to the extent of 555 examinations, chiefly for eyes, ears, and throats, and out of these cases 158 were operated on. The cases seen by specialists rose from 488 in the six months ending Dec. 31st, 1922, to 764 for the six months ending June 30th, 1924, while the operations rose from 121 to 220. The cost for these services ranged between £1240 in 1922 and £1697 in 1924 over a six-months' period, the cost in the complete year 1923 being £2842. Unfortunately the service as it is at present is a limited form and is not applicable to insured persons generally, but the fees set out on p. 3 of the report may form some guide to the calculation of the cost of a more inclusive service. At one centre the specialist charges two guineas a visit to the centre to examine eyes or throats, the number of cases treated to be not less than four, and operations were paid for at the rate of £1 2s. 6d. a case, including the anaesthetist. In other cases payments were made to hospitals, 5s. per case for the examination of eyes, and for operation cases not admitted as in-patients, £1 10s. There is clearly a

very well-running machine in Gloucestershire which could be made available at once for any extension of the insurance service.

TUBERCULOSIS.

Notification of Tuberculosis.—The Ministry of Health has issued new regulations, dated Dec. 18th, 1924, which came into operation on the first day of the New Year. According to these regulations, every medical officer of health must furnish at the end of each quarter a statement showing (a) the number of cases of tuberculosis on his register at the commencement of the quarter, (b) the number of cases notified to him under the regulations of 1912 for the first time during the quarter, (c) the number of cases removed from the register during the quarter (giving the name and address of each such case and the reason for such removal), and (d) the number of cases remaining on the register at the end of the quarter. Separate figures must be given in each case for males and females, and for pulmonary and non-pulmonary cases. In a circular dated Dec. 22nd, 1924, the Ministry of Health threatens with prosecution the medical practitioner who is remiss in notifying tuberculosis. He is reminded that a notification of tuberculosis made after the notifying practitioner is aware of the death of the patient is not a notification duly made, and it does not entitle the practitioner to the payment of the prescribed fee. The circular proceeds: "and it appears to the Minister that it may even be desirable to proceed to a prosecution in one or two cases. . . ." The problem to which this circular refers is not simple, and it is one that cannot be solved solely by admonitory injunctions from headquarters. The proportion of cases of tuberculosis not notified till after death varies considerably in different parts of the country, and, as a rule, this post-death-notification-rate may be taken as a rough guide to the degree of co-operation between medical practitioners on the one hand and medical officers of health and tuberculosis officers on the other. Another factor, influencing the post-death-notification-rate, is the amount of help extended in each district to the persons notified: it is obvious that the more a patient is helped consequent on notification, the greater will be the inducement to effect early notification.

Tuberculosis Administration in Lancashire.—The report of the central tuberculosis officer of the Lancashire County Council for 1923 shows that the county death-rate per 1000 in 1923 was 0.70, the lowest yet recorded. This reduction in the tuberculosis death-rate being greater than that for other diseases, it would seem justifiable to conclude that modern anti-tuberculosis measures are eminently rational. Further improvement has been made in reducing the number of omissions to notify tuberculosis, and in the year under review less than 7 per cent. of the deaths from pulmonary tuberculosis were notified after death. In 1918, 18 per cent. of all the notifications were made after death. Further evidence of the improving co-operation between medical practitioners and tuberculosis officers is to be found in the fact that 76.6 per cent. of the new cases (excluding contacts) examined by the tuberculosis officers had been referred to them by practitioners, pensions authorities, school medical officers, and other health officials. On pages 78 to 80 of this report the after-histories of 2228 patients, who completed sanatorium treatment, are compared with the after-histories of 1640 patients in a similar stage of the disease who did not undergo sanatorium treatment. The comparison is in favour of the sanatorium patient. The report is enlivened by the inclusion of photographs of patients at work and rest in the county sanatoriums. The work photographs are supposed to prove that "there are no loafers in the county sanatoria." Could any proof be more convincing?

Tuberculosis Control in Birmingham.—The tuberculosis work in Birmingham is of such a high order that the annual reports by Dr. G. B. Dixon, chief tuberculosis officer, are a source of inspiration. One

of the most admirable features of sanatorium administration in the Birmingham area is the provision of observation beds. Of the patients discharged from all the Birmingham sanatoriums during 1923, no less than 18 per cent. had passed through the observation beds at Yardley-road Sanatorium. In connexion with these beds it is pointed out that "in only a limited percentage of all cases is it possible to arrive at a correct diagnosis of pulmonary tuberculosis in the consulting room after one or two examinations. The provision of an adequate number of observation beds allows of an accurate diagnosis being made in a larger number of what would otherwise remain as doubtful cases." This lesson, that the one-consultation diagnosis is insufficient to act as a pivot on which the whole of the patient's future turns, is one which still requires emphasising.

HOSPITAL NOTES.

ROYAL NORTHERN HOSPITAL.—Thirty-two of the 60 closed beds will shortly be reopened. This has been made possible by the success of an effort to double a benefaction of £20,000 which was offered conditionally upon a similar sum being raised towards the reduction of debt by New Year's Day. There were more than 40,000 subscribers to the second £20,000.

TILBURY HOSPITAL.—Sir P. J. Michelli, secretary of the Seamen's Hospital at Greenwich, points out that the new buildings at the Tilbury Hospital are on the pavilion system and of one story only. They consist of a nurses' home, two wards of 25 beds each, an out-patient department, an operating theatre, and kitchens. Owing to the alluvial nature of the soil reinforced concrete "rafts" are necessary for the foundations. The walls are composed of hollow triangular cement and breeze blocks, two blocks forming a section of the outside wall, with a breeze block in the intervening triangular space. The cost per bed will be only £700. The grounds are being planted in advance of the building, in the hope that there will be well-rooted trees in leaf by the time the new wards are occupied.

POPLAR HOSPITAL FOR ACCIDENTS.—At the sixtieth annual festival dinner the Chairman, Sir Charles McLeod, stated that to meet the constantly increasing demands upon the hospital it had been necessary to enter into a contract for new work amounting to over £25,000. This hospital, which has 103 beds, was rebuilt in 1891 and has since been five times enlarged.

LONDON HOSPITAL'S CATGUT FACTORY.—Last year this factory produced £10,250 worth of catgut. Most of it was sold to other hospitals and to surgeons, and some was sent as far afield as Persia and China; the "London" itself used £550 worth. The profits are sufficient to enable the hospital to treat 1000 out-patients or to maintain three beds.

WEST LONDON HOSPITAL: NEW WING.—The sorely-needed new wing is rapidly approaching completion and will be opened next month by Princess Mary. It contains an accident ward of 16 beds, male and female cancer wards, each containing seven beds, two operating theatres, and 26 beds in private rooms for paying patients. The available beds will now number 220. The wing will be opened free from debt, thanks to the generosity of anonymous donors.

BRITISH HOSPITALS ASSOCIATION.—The annual conference will be held at Manchester on June 25th and 26th. Last year the association met in London and in 1923 at Sheffield.

NEW BIDEFORD AND DISTRICT HOSPITAL.—Lord Glanely has laid the foundation-stone of a new hospital for Bideford and the district, to take the place of an inadequate building erected in 1887. It will stand upon a high and quiet spot and will have 26 beds, with provision for extension; the building, designed by Mr. H. Deighton Pearson, will cost over £15,000. At the celebration dinner Dr. E. J. Toye, the Mayor of Bideford, said that he was the first medical practitioner

in North Devon to own a motor-car. He paid £400 for it; it cost 7s. 6d. per mile to run, and after two years he sold it for £20, less £7 for commission and carriage.

LIVERPOOL INFIRMARY.—The first wing of the new nurses' home of the Royal Infirmary, Liverpool, built at a cost of £40,000, was opened on Dec. 31st by the retiring matron, Miss E. M. Cummins. The completed wing is only one-third of the whole building, which will cost about £120,000. Dr. T. R. Glynn, emeritus professor of medicine of the University, reminded the representative audience that the old nurses' home, built in 1865, was the first institution of the kind in the kingdom. The new home, when completed, would be the largest in the country, accommodating 150 nurses.

MANCHESTER CHILDREN'S SANATORIUM AT ABERGELE.—The Public Health Committee of the Manchester City Council have presented a report on the proposed children's hospital or sanatorium at Abergel. There is a very large number of children in Manchester suffering from pulmonary and non-pulmonary tuberculosis, and the existing accommodation is totally inadequate to meet the demand—both as regards the number of beds and the type of treatment provided. The possibilities for modern treatment by sunlight are very restricted in the existing accommodation. Abergel provides an ideal site for the combination of open-air and sun treatment, as it has an altitude of nearly 500 ft. above sea-level and is only about two miles from the seashore. The site chosen is on the committee's estate and consists of 25 acres. The plans provide for a sanatorium for 546 beds, a school for 100 children, and covered playgrounds. The total cost for the complete scheme is £145,000. The City Council has already decided to provide 210 beds as the first instalment of the complete scheme.

WARD-NAMING AT YORK COUNTY HOSPITAL.—A practice not uncommon in French hospitals was introduced on Dec. 24th last at the County Hospital, when the names of four famous York medical men, two of the eighteenth and two of the nineteenth century, were commemorated by naming wards after them. One ward will be known as the "Burton," part of another ward as the "Drake," the remaining part of the same ward as the "Jalland," and the eye ward as the "Tempest Anderson." Dr. John Burton was the original of Dr. Slop in "Tristram Shandy," who seems to have incurred the enmity of Laurence Sterne through an attack on his uncle the Archdeacon of York. He was a notable obstetric surgeon of his period. Dr. Drake was the author of a history of York as well as a physician of merit.

A SUCCESSFUL HOSPITAL FUND.—During its last financial year the Bradford Hospital and Convalescent Fund, which helps to support the Bradford Infirmary, the Eye and Ear Hospital, the Children's Hospital, St. Catherine's Home, and the Workpeople's Convalescent Home, raised over £22,000. More than half of this sum was subscribed by workers in the mills and factories. Bradford Royal Infirmary, which will observe its centenary this year, has long been inadequate, and for some time past possibilities of reconstruction have been under discussion. Nearly 30 years have elapsed since the last enlargement.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED JAN. 3RD, 1925.

Notifications.—The following cases of infectious disease were notified during the week—namely, small-pox, 65; scarlet fever, 1835; diphtheria, 1083; enteric fever, 55; pneumonia, 1259; puerperal fever, 43; cerebro-spinal fever, 5; acute poliomyelitis, 7; encephalitis lethargica, 44; dysentery, 7; ophthalmia neonatorum, 99. There were no cases of cholera, plague, or typhus fever notified during the week.

Deaths.—In the aggregate of great towns, including London, there were 6 deaths from enteric fever, none from small-pox, 13 from scarlet fever, 41 from diphtheria, 62 from measles, and 100 from influenza. In London itself the deaths from diphtheria numbered 8, from whooping-cough 30.

Correspondence.

"Audi alteram partem."

THE PATHOLOGY OF PYORRHOEA.¹

To the Editor of THE LANCET.

SIR,—In an article in your issue of last week summarising Dr. Box's work on pyorrhoea, you paid me the compliment of referring specifically to my view as to the nature of that disease. By inference you made it clear that you would not expect me to endorse all Dr. Box's contentions, and therein you are right. May I ask a short space to outline my reasons? Dr. Box's main thesis seems to be that "traumatic occlusion" induces an internal disease "rarefying pericementitis fibrosa," which opens the way to bacterial infection from the periodontal sulcus. My position is that all the disease subdivisions he enumerates, including "rarefying pericementitis fibrosa," are of the nature of an infection which gains access from the periodontal sulcus—that the beginning is always a marginal gingivitis. I base my opinion on clinical observation.

On the "traumatic occlusion theory" the perfect arch, with perfect occlusion of all 32 teeth, should be practically immune to pyorrhoea. Unfortunately the reverse is the case; the perfect arch is also a perfect breeding ground for pyorrhoea, a point which can be readily apprehended when its capacity for retaining fine-ground sticky food in hidden stagnation areas is appreciated. An exaggeration of this condition is seen in the irregular dental arches so often found in association with "adenoids."

On the other hand, there are people with normally shaped dental arches, but naturally deficient in number of their teeth, and in these people the deficiency in number is often accompanied by spacing of the teeth they do possess. There are also others who have had teeth extracted in early life in such a way as to allow of spacing of the remaining teeth. In both these classes normal occlusion is utterly disorganised and "traumatic occlusion" must be rampant, yet the clinical fact is that they are markedly less liable to pyorrhoea because, in a word, drainage is easier. A very striking illustration of this may sometimes be seen in cases where unilateral extraction has been practised in early life; the extracted side will be found free from pyorrhoea, decay, or tartar, while all these conditions are all well developed on the other. Further, "traumatic occlusion" might be supposed, at first at least, to give rise to a physiological response and so to require time to do its evil work; in fact, marginal gingivitis and pyorrhoea are common from childhood onwards, giving scant time for the antecedent "traumatic occlusion" and "pericementitis fibrosa."

Again, clinical observation of the results of treatment leads me to expect far better results in the case of isolated teeth, whatever their occlusion, than in the case of teeth supported by their neighbours. Cleaning of the last millimetre of the exposed tooth-neck is then possible, and this cleaning is the most efficacious conservative treatment I have yet found.

Turning to another point, I think Dr. Box tends to minimise the dangers of pyorrhoea when he insists that after a primary ulceration of the angle of the periodontal sulcus re-epithelialisation of the ulcerated area takes place, and that this progressively follows the deepening pocket. I have cut many sections and my experience is that there are always ulcerated areas to be found, and though there is often abundant epithelial proliferation it never forms a complete covering to the tooth-ward side of the gum-flap.

¹ Copies of Bulletin No 7 containing Dr. Box's Studies in Periodontal Pathology may be obtained from the Secretary, Canadian Dental Research Foundation, 240, College-street, Toronto (price \$1). A limited number of Bulletins covering Dr. Box's previous work on the Dental Cemental Junction and Normal and Pathological Histology of the Dental Pulp will be supplied upon application by the Foundation.

May I ask one line more of space—to congratulate Dr. Box most heartily on his work.

I am, Sir, yours faithfully,

London, Jan. 11th, 1925.

J. G. TURNER.

ALASTRIM, PARA-SMALLPOX, AND VARIOLA.

To the Editor of THE LANCET.

SIR,—In the correspondence on the subject of alastrim as against small-pox in your issue of Jan. 10th and in the various other articles which have been published from time to time on the same subject, frequent reference is made to the Willesden outbreak of small-pox which occurred last summer. As all the cases, ten in number, which occurred in that outbreak were under my care, perhaps an account of the more salient features in connexion with them may help to clear up the question as to whether alastrim and small-pox are one and the same disease or two separate diseases.

To begin with, the original source of this outbreak is unknown. It was suggested, however, possibly because there were three fatal cases and the type of small-pox prevalent in this country was benign, that the source of infection was imported from abroad, but nothing definitely in that direction was proved. A much more likely source of the trouble, to my mind, was that a mild and undetected case of small-pox was possibly at large in the district, and the possibility of this is not at all unlikely if one remembers that large numbers of people from the Midlands, where small-pox is rife, were passing through Willesden on their way to Wembley, and that en route some of them resided temporarily in the district. Referring now to the first case of the outbreak (E. W.), a child of 3 years, who first developed symptoms on June 9th, the subsequent cases developing some 12 days after, the attack that this primary case suffered from was of the mildest. Perhaps if I say the premonitory symptoms were of the usual nature associated with that type of small-pox but sufficient to keep him to his bed for three days, and if I enumerate the number of lesions on the various areas of the skin surface, a better idea of the exact nature of the case may be gained than by any written description. The following list gives the number of lesions and the sites on which they were situated:—

Face	6	Legs and feet .. .	33
Forehead .. .	2	Upper back .. .	4
Upper chest and chest ..	4	Lower back .. .	20
Lower chest and abdomen ..	7	Upper arms .. .	21
Thighs .. .	25	Forearms and hands ..	18

Of the total of ten cases which constituted the outbreak, six suffered from attacks of the mildest nature, and of these three were in unvaccinated children, whilst the remaining four developed attacks of the severest type, two patients being unvaccinated. Of these four severe cases three died from hæmorrhagic small-pox (purpura variolosa) in its worst forms, the fourth case, an unvaccinated man, recovering after a moderately severe confluent attack.

In the instructive and very interesting articles on alastrim by Prof. R. Jorge, lately appearing in THE LANCET, and in the descriptions of this disease appearing elsewhere, the writers have so clearly mapped out their idea of alastrim that no vestige of doubt is left in the minds of readers as to the exact appearance that alastrim assumes. Having therefore a clear conception of the clinical aspect of the disease, I have no doubt in my mind that the six mild cases in the recent outbreak here met in every detail that I could see the requirements of alastrim as set out by its protagonists, and I would at the same time submit, and I base the statement on a fair experience of small-pox during the last 30 years, that these six cases in no way varied from mild cases of small-pox such as were to be seen in London in the epidemics of 1893 and 1902, and such as are to be found in every outbreak of small-pox of any size in a large proportion of cases. With regard to the remaining four cases, all of them

severe, three of which were fatal, there will be no dispute, least of all by the supporters of alastrim, that these were other than small-pox.

As I read the case for alastrim it is contended that this disease differs from small-pox inasmuch as it does not seem to be so infectious, in this country at any rate, as small-pox; it is said to be mild, is rarely fatal, and furthermore, that the date of appearance of the rash and subsequent vesiculation, pustulation, and non-scarring of the skin is said to be quite out of keeping with what occurs in that disease. Taking these points in sequence.

First as regards infectiousness. Although the outbreak in Willesden only affected one house, every member of the household was attacked, but, on the other hand, it remains a fact that one case, a man of 40 years, spent the afternoon of the day on which he developed the eruption on a 'bus ride to Wembley. Yet no further cases developed in consequence. One single instance of this kind proves nothing, but had there been no fatalities amongst the ten cases, no doubt the outbreak would have been labelled alastrim, and the fact that such a circumstance led to no further cases would have been duly laid stress upon. Again, with regard to the date of appearance of the rash. Alastrim is said to develop its rash at a more variable and later date than small-pox, which seems to suggest that the eruption in small-pox is always to be found on one particular day of the disease, but to anyone conversant with small-pox that is known not to be the case. With regard to the statement that the eruption in alastrim appears at a later date than small-pox, and before accepting it, especially as regards alastrim in this country, I should like to be convinced that the dates on which the eruption is said to appear are the outcome of the personal observation of the medical officer in charge and not based on the mere statement of the patient. Everyone knows that the day on which the patient notices the rash is not necessarily the day on which the rash actually appears, yet there is good reason to believe that data on this particular point are based on information supplied by the patient himself. However, I do not wish to labour the point. With regard to the date on which the ten cases in this district developed their rashes the following are the figures. In two cases the eruption appeared on the third day of illness, in six cases on the fourth day, and in one case on the fifth day, whilst in the tenth case the patient died before the specific eruption appeared.

Referring now to the subsequent development of the eruption in these cases, the most remarkable feature was the way in which the phases of papulation, vesiculation, and pustulation were epitomised, and this was as marked in the unvaccinated as in the vaccinated cases. Moreover, in no case, not even in the confluent case, could complete pustulation be said to be present. This phase was always ill-defined and this feature was remarked upon by all who saw the cases. The vaccinated cases in this respect showed no difference when compared with the unvaccinated. At the height of such suppuration as took place the pustules were dome-shaped, but never pronounced in size or definitely suppurating throughout. They remained a clear yellow serum with opaque streaks, and might well be called amber-coloured, a term used aptly enough by Dr. Garrow in a paper on para-smallpox recently read by him to the Fever Section of the M.O.H. Society in London, when describing the colour characteristics peculiar to the pustules in that disease. In none of the cases did the pustules burst in the orthodox way, an inspissation of the contents of the pustule gradually transformed it into a dry scab which readily separated, leaving nothing but the most superficial of scars on the skin, such as might be expected in a case of varicella.

The Willesden outbreak is therefore definitely in favour of the unicist. There could be no possibility of a double source of infection. The primary infecting case was very definitely a mild attack in an unvaccinated member of the family in which the outbreak occurred, and to which and the other occupants of

the house the outbreak was limited. It gave rise to nine cases, four of which were indisputably small-pox; the remaining six (including the primary case), in the opinion of those who saw them, being ordinary mild small-pox, but which at the same time conformed in every clinical detail with the requirements of alastrim.—I am, Sir, yours faithfully,

W. J. J. STEWART,

Medical Superintendent, Willesden Fever Hospital, London, N.W.

Jan. 10th, 1925.

SMALL-POX OR PARA-SMALLPOX.

To the Editor of THE LANCET.

SIR,—I have read Prof. Ricardo Jorge's memoir, appearing in THE LANCET of Dec. 20th and 27th, with much interest. Undoubtedly, it is a valuable contribution to the literature of the subject, but his conclusions are too important to pass unchallenged. It is indisputable that the non-virulent strain of small-pox which has been occurring in this country during the past few years and which, as Prof. Jorge shows, has frequently been experienced in other parts of the world, presents a very different administrative problem from the so-called "classical" small-pox. As you, Sir, have pointed out in your leading article on the subject (THE LANCET, Jan. 3rd), attempts to treat outbreaks of the present non-virulent strain of small-pox just as if it were a virulent strain only tend to bring administrative action into contempt and disrepute.

Some distinction in terminology is, I think, called for, but not such as to imply that we are dealing with a separate and distinct disease. From the administrative point of view there is certainly something to be said in favour of Dr. Garrow's suggestion of the term "para-smallpox," but from the scientific standpoint such a term can only be justified when—as in the analogous case of para-typhoid—we have succeeded in demonstrating a definite and distinctive causative organism. In the meantime, however, the thesis of the "dualists" that alastrim or para-smallpox is a distinct pathological entity does not appear to me to have been made out. It is merely a surmise based upon a difference in virulence and not supported by any specific clinical differences at all adequate in view of the great importance of the issue.

We have to remember that differences in the virulence of small-pox have ever been a characteristic of the disease. In pre-vaccination times the fatality of different epidemics at different periods varied enormously, though we can easily understand that the more fatal and disastrous epidemics were the ones chiefly recorded in the pages of literature. Only on the hypothesis that much of the small-pox of pre-vaccination times was very mild can we account for the fact that the disease, which almost everyone contracted at some period of his life, did not depopulate the country. Moreover, since the vaccination controversy arose there has been a tendency in text-books to unduly emphasise the heavy fatality of small-pox before the days of vaccination and to rather over-paint the picture.

In this connexion the experience of Leicester is of special interest because, to a larger extent than elsewhere, we have been dealing (since 1885) with the behaviour of small-pox in a comparatively unvaccinated population. In 1872 there was an epidemic of severe small-pox and 346 deaths occurred. The case-mortality is unknown, but undoubtedly it was high. In 1892-93, in the next epidemic, there were 355 cases with 21 deaths, a case-mortality of only 5.9 per cent. In the epidemic of 1902-03, 394 cases occurred also with 21 deaths, a case-mortality of 5.3 per cent. In the epidemic of 1903-04, 321 cases occurred with only four deaths, a case-mortality of only 1.2 per cent. Clinically the cases in this epidemic were indistinguishable from those I saw at Gloucester in 1923, though the average severity was slightly higher.

Naturally, with the experience of this epidemic in my mind, I was less disposed to marvel at the mildness

of the Gloucester epidemic than were some of those who had been taught to believe that small-pox in the unvaccinated is almost invariably a terrible and fatal disease. If we were to have another epidemic in Leicester to-day it is not unreasonable to think that the fatality would be still lower.

But here is the difficulty: So-called alastrim or para-smallpox occasionally causes deaths, as Prof. Jorge admits. Even at Gloucester there was at least one genuine death from small-pox. Then, where are we to draw the line between small-pox and para-smallpox? Was the Leicester epidemic of 1903-04, with a case-mortality of only 1.2 per cent., small-pox or was it para-smallpox? And if the latter, what was the nature of the epidemic of the previous year with a case-mortality of 5.3? What are the criteria on which we are to decide? Frankly, after reading Prof. Jorge's memoir carefully, and also the writings of Dr. Garrow, the chief "dualist" in this country, I fail to find any essential difference, clinical or otherwise, between small-pox and para-smallpox except that of virulence. Such apparent differences as there may be are not specific and can easily be explained as being due to differences in virulence. They do not justify us in postulating a distinct disease, still less do they enable us to make a differential diagnosis.

We have a very analogous case in scarlet fever. If a medical Rip van Winkle were to return to practice after an absence, say, of 50 years, he might make out just as good a case for the proposition that the mild non-fatal "scarlatina" which he found filling the fever wards of our isolation hospitals to-day was a different and distinct disease from the dreaded scarlet fever which he remembered, and which not infrequently carried off several members of the same family. He could point to the comparative absence of constitutional disturbance, of angina, "strawberry" tongue, and other "classical" symptoms, and the freedom from the numerous dreaded complications and sequelae. But we should rightly object to his calling it para-scarlet fever!

To return to small-pox; I think that there is much more to be said in favour of Dr. R. W. Jameson's suggestion in his article in this week's LANCET (Jan. 10th). This article is so refreshingly original, and is so full of sound common-sense, that I commend it to all who are interested in small-pox and its administrative control. Dr. Jameson suggests that we should call the present non-virulent small-pox "variola minor," using the term "variola major" for the classical form. Such a terminology has certain obvious administrative advantages, whilst avoiding the confusion introduced by the term "mild small-pox" at present in use. Also it does not commit us to the theory, as yet, I submit, unjustified, that we have to deal with a distinct disease—or even a definite variety—though it does not shut the door on those who prefer to hold this theory.

I am, Sir, yours faithfully,

Leicester, Jan. 12th, 1925. C. KILLICK MILLARD.

FATE OF THE BULBUS CORDIS.

To the Editor of THE LANCET.

SIR,—I had the privilege of hearing Sir Arthur Keith's lecture on the Fate of the Bulbus Cordis in the Human Heart at the London Hospital, which appeared in your issue of Dec. 20th, 1924. Illuminating in demonstration and charming in delivery, like most essays of this author, as the lecture was, there are one or two points on which, with your permission, I should like to make a short comment.

While there are probably a few cases of valvular adhesion in foetal life, which may still be attributed to intra-uterine endocarditis, there can be no doubt that the vast majority of congenitally abnormal hearts are malformations—that is, failures or arrests in development. Sir Arthur Keith's papers published in the *Journal of Anatomy and Physiology* in 1904-5, and in

THE LANCET in 1909, sufficiently proved this thesis, and now that he has so fully and lucidly stated the point again, the clinician will not be able, in my opinion, to avoid endorsing his contention.

The points dealt with are interesting clinically as well as anatomically. The early obstruction of the bulbar avenue and pulmonary outlet forces the blood-stream towards the left heart through abnormal or temporary channels in the ventricular or auricular septum, a diversion which may, under some conditions, be compatible with considerable length of life. One such case in a man of 72, in which the right ventricle was underdeveloped and the pulmonary arterial valve all but obliterated, but the foramen ovale very large and patent, I published in the *Journal of Anatomy and Physiology* in 1917-18. In a paper on the Musculature of the Aorta and of the Cardiac Valves, Anatomically, Physiologically, and Clinically Considered (*Edin. Med. Jour.*, September, 1923), I dealt with a point discussed by Sir Arthur Keith—namely, the persistence of the elasmobranch or shark type in the condition of the conus arteriosus in man. On the possible function of the bulbus in the fish, he makes an interesting comment. He is inclined to regard it as protective of the circulation through the gills. Longitudinal sections, as anyone may satisfy himself, of the heart, bulbus, and aorta, in elasmobranchian and teleostean fishes, show that in the former the bulbus—that is, the heart muscle—extends up the wall holding the ladder of multiple valves, just to the point which secures effective embracement of the whole series of cusps, and in teleosteans, to a point embracing the single set of cusps, beyond which lies the large non-contractile bulbus, which is really the strong base of the aorta.

Sir Arthur Keith suggests that the bulbus cordis in these cases serves to protect the delicate gill circulation from the powerful impulse of the single ventricle. It appears to me, however, that driving the blood through the systemic arteries of the fish is probably an easier matter than maintaining the circulation through the gills, which are exposed to heavy hydraulic pressure, and the deeper the fish lies, the heavier the pressure. As we know, the gill arteries are more directly exposed to this pressure than the gill veins. The contractile bulbus of the cartilaginous elasmobranch and the fibrous non-contractile bulbus of the bony teleostean both thus appear to serve the purpose of enforcing ventricular push and guarding against bulbo-gill variations of pressure. The steady maintenance of pressure in the pulmonary circuit in man is important. The retentive power of inspiration on the circulation and the projective influence of expiration are equalised by the contraction of the conus, which can be shown to precede left ventricular systole, as Sir Arthur Keith suggests in his lecture, and as I indicated in the paper to which I have referred.

On one more point, which I regard as both interesting and important, I would remark. The lecturer stated (*loc. cit.*, p. 1271) that the musculature of the internal or aortic cusp of the mitral valve is the only remains of "the lesser curvature of the bulbo-ventricular tube of the primitive heart" on the left side. In the paper to which I have referred I showed that this important remnant was not only in organic continuity with the general auricular muscle, but that it was also an integral part of a distinct sphincter of the auricular orifice, and a powerful aid in securing mitral valvular competency. It is an interesting structure not only anatomically but also clinically, for its weakening in auricular fibrillation and under some other circumstances, permits that mitral reflux which is no longer the negligible condition it was so loudly proclaimed to be not long ago. The character of this sphincter as a bulbo-ventricular remnant supports the view I expressed (*loc. cit.*) that its contraction persists during ventricular systole—that is, when the rest of the auricle is in a condition of receptive relaxation. It is the last auricular act, and manifestly could not be otherwise.—I am, Sir, yours faithfully,

ALEXANDER BLACKHALL-MORISON.

London, Jan. 3rd, 1925.

BRONCHO-PULMONARY SPIROCHÆTOSIS.

To the Editor of THE LANCET.

SIR,—We were much interested in Dr. Y. Schwarz's account of broncho-pulmonary spirochætosis in THE LANCET of Dec. 27th, 1924, inasmuch as there is at present in this sanatorium a similar case, the history being as follows:—

Man, aged 40, eight years ago suddenly spat up a lot of foul-smelling chocolate-coloured material; this went on for some days, gradually becoming paler in colour, greenish, and finally yellow, and disappearing in a few weeks. The patient then kept perfectly well with no cough or sputum until three years ago, when exactly the same thing happened again. He once more recovered and had no trouble until his present attack, which commenced five months ago with the same train of symptoms. This attack, however, has been more severe than the previous ones, and the sputum is not disappearing as it did before. It went through the same stages—that is to say, chocolate-coloured and foul-smelling, gradually becoming paler,

FIG. 1.

Radiogram: light in front.

green, and then yellow. It is now, and has been for some weeks, at the yellow stage. The patient has lost 1 st. 11 lb. in weight, but is not toxæmic at present. The pulse is slow and good, there is as a rule no fever, and the appetite and general condition are satisfactory. There have been also some small attacks of hæmoptysis. The patient has lived for the last 15 years in Singapore, and he recovered from the first two attacks without leaving Singapore. However, owing to the prolonged nature of the present attack, he was sent to Switzerland, and finally was admitted into the Palace Hotel Sanatorium, Montana, on Dec. 17th, 1924.

This patient is at present being treated by regulated sun baths, and by injections every five days of neosalvarsan. We shall watch with great interest the progress of the case, and if the conditions have not cleared up we shall in all probability attempt to close up the lesion by inducing an artificial pneumothorax. Unlike the cases described by Dr. Schwarz, the X ray signs, as is seen in the accompanying radiograms, were quite definite and not unlike those of an interlobar empyema. The sputum has been examined frequently since the patient was admitted to the sanatorium, and the organisms of Vincent's angina—both spirochæte and fusiform bacilli—have constantly been found in the dark-ground illuminator, in silver stain, Giemsa, and ordinary stains.

In connexion with the suggestion contained in Dr. Schwarz's article, that the fusiform bacillus may be another form of the spirochæte, it is interesting to note that when the sputum was examined by Prof. Galli-Valerio, of Lausanne University, on Dec. 11th, 1924, this fusiform bacillus was present in large numbers, but no spirochætes were then found.

We are, Sir, yours faithfully,

BERNARD HUDSON.

A. J. MORLAND.

E. ZIMMERLI.

Montana, Switzerland, Dec. 31st, 1924.

INDIVIDUAL RESISTANCE IN THE CURE OF MALARIA.

To the Editor of THE LANCET.

SIR,—In the Critical Consideration of the Treatment of Malaria by Colonel Clayton Lane in the November number of the *Tropical Diseases Bulletin*, one reference

only is made to the resistance of the individual as being of importance in the cure of malaria, while your leading article of Jan. 3rd appears to take the line that the one and only factor of importance in the treatment of malaria and the prevention of relapses is the giving of quinine and to have in mind only that the essential idea should be to find out the best dosage, the most potent preparation, and the appropriate period for the administration of the drug.

Failure to realise and allow for the factor of the resistance of the individual

seems to me to explain much of the difficulty associated with the cure of malaria. I have only occasionally, among very many cases, come across the difficulties that were met with in war-time patients, but then my practice, even during the years of the war, has been confined to malarial patients who were living under peace conditions, and when difficulties did occur they were found to be due to some associated disease which caused a detrimental interference with the resistance of the individual.

It is, of course, elementary that the severity of a disease varies with the relation of the dosage of the infection to the resistance of the individual. Resistance can be lowered in many ways, but one of the most potent must have been the conditions of war service under which, in addition to numerous physical hardships, the ever-present expectation, almost amounting to certainty, of wounds and death can hardly have been other than a cause of depressed resistance.

The treatment of peace-time malaria is easy and commonly successful. Failure may be due to faulty quinine administration or to concomitant infections which will require to be dealt with if the patient is to recover quickly and satisfactorily.

I am, Sir, yours faithfully,

London, W., Jan. 9th, 1925.

GLUT OF WOMEN DOCTORS.

To the Editor of THE LANCET.

SIR,—As showing the glut of women doctors the following figures may be of interest. To-day there were 78 applicants for the post of junior resident medical officer (female) at the Children's Hospital, Sunderland, salary £100 a year. Thirty-three held English qualifications; 33 Scottish, and 12 Irish. Of the English qualifications ten were London graduates, four Durham, two Birmingham, one Sheffield, seven Manchester, and six London Conjoint Colleges. Of the 33 Scottish qualifications three were of St. Andrews, nine of Edinburgh, 13 of Glasgow, and eight of Aberdeen. Of the 12 Irish qualifications seven were of Belfast, three of Dublin University, and two of Irish Conjoint Colleges. Forty-five out of the 78 had held previous public appointments, and many of them had held several.

I am, Sir, yours faithfully,

Sunderland, Jan. 13th, 1925.

WM. ROBINSON.

ERASURE FROM THE MEDICAL REGISTER.

To the Editor and Proprietors of THE LANCET.

DEAR SIRs,—In THE LANCET's report of proceedings at the General Medical Council's winter session, which opened on Nov. 25th, there appears a reference to my case, considered by the Council, which in more than one respect is likely to create a serious misunderstanding, on the part of readers, that may be damaging to me.

It is incorrect to report that "Dr. Haydn Brown attended in answer to his notice and explained that he had really no answer to make to the charge, but that he was ready to reply to any questions put to him." My reply was that I had little to say "beyond what was contained in my written replies to the charge as sent to the Registrar and to the solicitor of the Council respectively."

The members of the Council were each supplied with a copy of the double reply, which consisted of no less than 18 quarto typewritten pages.

I must therefore ask you to be kind enough to correct the injurious impression by publishing this letter in a prominent position in an early issue of THE LANCET, as well as the 18 quarto pages referred to—which I enclose.—Yours faithfully,

HAYDN BROWN.

Cavendish-square, W., Jan. 8th, 1925.

*** Dr. Haydn Brown gives his opening words correctly. Our report might have added that certain written replies had been sent, but it could not include these documents of which the contents were not made public.—ED. L.

REX v. BATEMAN.

IN view of an Appeal which we understand is pending in this case we are unable to publish the letters which we have received this week.

MANCHESTER STREETS AND THE TOLL OF THE MOTOR.—During 1924 the Chief Constable of Manchester reports that there was a much larger number of street traffic accidents in the city than in 1923. The number of fatal accidents was 68; in 1923 there were 48. The following classification shows the details—the numbers in brackets indicate the corresponding numbers in 1923. Horse-drawn vehicles 9 (6), mechanically-propelled vehicles—motor-cars, omnibuses, &c.—40 (36), tramcars 9 (5), pedal cycles 1 (2). There were 1655 non-fatal accidents compared with 1386 in 1923, an increase of 269, classified as follows: Horse-drawn vehicles 93 (64), mechanically-propelled vehicles 1055 (964), tramcars 280 (197), pedal cycles 227 (161). Motor vehicles were concerned in most of the accidents, and many occur at tram stops. The corporation has tried repeatedly to obtain powers from Parliament to regulate traffic at the tram stops, so as to reduce the danger to a minimum. Last year a clause in a Corporation Bill which would have compelled motor vehicles to pull up at the compulsory tram stops when cars are standing there was rejected by the House of Lords on the ground that the subject was one for general rather than local by-law.

Medical News.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—At a quarterly meeting of the Council of the College on Jan. 8th, Sir John Bland-Sutton, President, in the chair, Mr. Herbert S. Pendlebury was introduced, and having made the declaration in the terms of the oath prescribed by the Charter of 1800, was readmitted a member of the Court of Examiners.—Mr. Richard Higgins Burne, M.A. was awarded the honorary gold medal of the College in recognition of his valuable services to the College as Curator of the Physiological Department of the Museum and his important contributions to biological science.—The John Hunter Medal, with the Triennial Prize, was awarded to Mr. W. E. Le Gros Clark for his researches in anatomy.—Mr. Percy Sargent was appointed a member of the Court of the University of Bristol.—A letter from the Secretary to the Anatomical Committee of London stating that the licensed teachers of anatomy in London regret to report that the number of bodies available for teaching anatomy and operative surgery had diminished appreciably during the past year, and that they accordingly beg the Council to reconsider the question of requiring candidates for the M.R.C.S. examinations to produce evidence of having performed operations on the dead body until an improvement in the supply of material can be reported, was referred to a committee to consider and report thereon.—The President reported the retirement of Mr. John Murray from the Court of Examiners on Feb. 12th and stated that the vacancy thus occasioned would be filled up at the ordinary meeting of the Council on that day.

The under-mentioned diplomas were conferred, conjointly with the Royal College of Physicians of London, upon the following candidates:—

DIPLOMA IN PUBLIC HEALTH.

Dora M. Berry, J. Bevan-Jones, Hilda A. Bond, and N. Briggs, Univ. Coll.; W. H. Brodie, Aberdeen; E. B. Brooke, St. Bart.'s; Ellinor M. Burnett, Univ. Coll.; E. H. Cluver, Oxford and Johannesburg; E. A. Coldrey, St. Bart.'s; A. Y. Dabholkar, Bombay and Roy. Inst. Public Health; A. A. Denham, Edinburgh, Cambridge, and Roy. Inst. Public Health; Evelyn B. G. Ewen, Edinburgh and Univ. Coll.; C. Glen, Glasgow; Gertrude E. Harre and Eva M. Johnson, Univ. Coll.; J. Kapoor, Punjab and Univ. Coll.; Margherita M. Lilley, St. Andrews and Univ. Coll.; A. Mitchell, King's Coll.; W. E. M. Mitchell, St. Bart.'s; R. A. Olphert, St. George's and Univ. Coll.; I. M. Rattray, Cambridge, St. George's, and King's Coll.; G. C. E. Refell, Durham and Roy. Inst. Public Health; L. R. Shore, St. Bart.'s; H. K. Snell, King's Coll.; Eleanor C. E. Stone, St. Mary's and Univ. Coll.; Eileen M. Turner, Univ. Coll.; and R. G. R. West, St. Bart.'s.

DIPLOMA IN TROPICAL MEDICINE AND HYGIENE.

T. N. Banerjee, K. S. Captain, R. P. Cormack, D. M. de Silva, W. H. Dye, D. H. C. Given, H. P. Hacker, R. J. Harley-Mason, D. Hynd, Honoria S. Keer, R. N. Khosla, G. Louw, Una F. M. Morton, S. L. Navaratnam, D. It. Nayar, J. A. O'Flynn, H. C. E. Quin, C. F. Shelton, P. N. Suri, E. W. Wade, and H. O. Watkins-Pitchford.

DIPLOMA IN PSYCHOLOGICAL MEDICINE.

A. H. G. Burton, C. H. Comerford, E. H. Connell, G. W. T. Fleming, F. McLagan, W. G. Masfield, G. Somerville, and M. L. Sutcliffe.

DIPLOMA IN LARYNGOLOGY AND OTOLGY.

N. S. Carruthers, B. Friedman, F. B. Gillespy, W. G. R. Hore, G. W. Robinson, and D. A. Thomson.

UNIVERSITY OF OXFORD: RADCLIFFE TRAVELLING FELLOWSHIP, 1925.—An examination for a Fellowship of the annual value of £300, and tenable for two years, will be held in Hilary Term, 1925, beginning on Tuesday, Feb. 17th, at 10 A.M. Candidates must have passed all the examinations required by the University for the degree of Bachelor of Arts and for the degree of Bachelor of Medicine. They must not have exceeded four years from the time of passing the last examination required for the degree of Bachelor of Medicine. The examination will occupy four days. Papers will be set in physiology, pathology, and preventive medicine, and a subject will be proposed for an essay. There will also be a practical examination in pathology. Any candidate desiring to offer in addition a special branch of either medicine or surgery must send notice of this to the Regius Professor of Medicine on or before Feb. 4th. The successful candidate must before election declare that he intends to devote himself during the period of his tenure of the Fellowship to the study of medical science and to travel abroad with a view to that study. The Fellowship will be vacated ipso facto by a Fellow who spends more than nine months of the tenure within the United Kingdom. The Regius Professor of Medicine and the examiners present

a yearly report on the work done by each Fellow to the electors, who may, if they think the report unsatisfactory, declare the Fellowship forfeited. Intending candidates should send their names, addresses, qualifications, &c., to the Regius Professor of Medicine, at the Dean's Office, Department of Medicine, University Museum, Oxford, on or before Wednesday, Feb. 4th.

The degree days in the coming term are as follows: Thursday, Jan. 22nd, Saturday, Feb. 14th, and Saturday, March 28th, at 2.30 P.M. respectively.

UNIVERSITY OF LONDON.—A course of eight lectures on Carbohydrate Metabolism will be given by Mr. J. A. Hewitt, Ph.D., D.Sc., lecturer in biochemistry in the University, at King's College, Strand, W.C., at 5 P.M. on Mondays, Jan. 19th and 26th, Feb. 2nd, 9th, 16th, and 23rd, and March 2nd and 9th; also a course of 12 lectures on the Physiology of Muscle and Nerve will be given by Prof. A. V. Hill, F.R.S., Jodrell Professor of Physiology in the University, at University College, at 11 A.M. on Fridays, Jan. 23rd and 30th, Feb. 6th, 13th, 20th, and 27th, March 6th, 13th, 20th, and 27th, and April 3rd and 10th. Attendance at either of these courses is recognised in connexion with the B.Sc. (Honours) Degree in Physiology.—A course of three lectures on the Anatomy and Physiology of the Sympathetic Innervation of the Striated Muscle prepared by the late Prof. John Irvine Hunter, M.D. (of the University of Sydney), will be given by Dr. G. Elliot Smith, professor of anatomy in the University, at University College, Gower-street, W.C., at 5 P.M. on Mondays, Jan. 19th, 26th, and Feb. 2nd.—A course of six lectures on the Physiology of Reproduction will be given by Dr. A. S. Parkes, at University College, at 5 P.M. on Thursdays, Jan. 22nd and 29th, and Feb. 5th, 12th, 19th, and 26th.—A course of four lectures on the Physiology of Plain Muscle will be given by Prof. C. Lovatt Evans at St. Bartholomew's Hospital Medical College (Physiology Department, 6, Giltspur-street, E.C.), at 5 P.M. on Wednesdays, Jan. 14th, 21st, and 28th, and Feb. 4th. Admission to all the above courses of lectures is free.

MEDICO-LEGAL SOCIETY.—A meeting will be held at 11, Chandos-street, Cavendish-square, W., on Tuesday, Jan. 20th, at 8.30 P.M., when a paper will be read by Mr. F. Llewellyn Jones, H.M. Coroner for Flintshire, on Laws of Nations and the Health of Nations: A Survey of International Health Activities Before and After the Great War. This will be followed by a discussion.

ST. MARY'S MEDICAL WOMEN'S ASSOCIATION.—At a meeting of St. Mary's women, past and present, held on Nov. 27th, 1924, it was decided to form an association, to be known as the St. Mary's Medical Women's Association. Its objects are those of a social club and a mutual aid society. Any woman educated at St. Mary's Hospital, Paddington, who, by an oversight, may not have received notice of the formation of this association, is asked to communicate with the Hon. Secretary, Mrs. Bolton, East Weald, Bishop's-avenue, London, N. 2.

ROYAL MICROSCOPICAL SOCIETY.—The annual meeting of this society will be held in the Lecture Hall, 20, Hanover-square, London, W. 1, on Wednesday, Jan. 21st, at 8 P.M., when Mr. A. Chaston Chapman, F.R.S., will deliver the presidential address on the Yeasts: A Chapter in Microscopical Science. The Industrial Applications Section will meet in the Lecture Hall on Wednesday, Jan. 28th, at 7 for 7.30 P.M., when a number of communications dealing with the Use of the Microscope in the Dairying Industry will be read and discussed. Prof. R. Stenhouse Williams will preside.

KING EDWARD'S HOSPITAL FUND FOR LONDON.—A meeting of the general council of this Fund was held on Jan. 13th at the offices of the Fund, 7, Walbrook, London, E.C. There were present Lord Stuart of Wortley (in the chair), Major-General Sir Cecil Lowther (hon. secretary), Dame Louisa Aldrich-Blake, Sir Cooper Perry, Mr. Leonard L. Cohen (hon. secretary), Mr. W. J. H. Whittall. The order of appointment, signed by the President, of the members of the general council, members of committees, and officers, respectively, for the year 1925 was read. The resolutions providing for the work of the Fund for 1925, which were approved at the meeting of the President and general council held at St. James's Palace on Dec. 16th, 1924, were formally adopted.

ELIZABETH GARRETT ANDERSON HOSPITAL.—In aid of the extension appeal fund of this hospital a concert was held under the auspices of the National Sunday League in the Palladium, Oxford-street, London, W., on Sunday, Jan. 11th. The concert was organised by Miss Marie Tempest, assisted by Miss Miriam Warner, and an excellent programme

of songs, instrumental music, and amusing parodies was rendered by well-known artistes, including Mr. T. Durac Minogue, Miss Grace Ivell and Miss Vivian Worth, Miss Elizabeth Pollock, the "Kansas City" Syncopated Band, Mr. Hubert Eisdell, Mr. Morland Hay, Miss Marion Browne, Mr. Ernest H. Mills, Messrs. Layton and Johnstone, Mr. Ivor Walters, Miss Clara Serena, the Gresham Singers, and Mr. Laurence Anderson. Dame May Whitty said a few words on the work done by the hospital and its present needs. The site of the proposed extension had been acquired through the generosity of an American lady, the late Mrs. Lorillard, who left a legacy of £10,000 to the hospital; £75,000 were now required to construct the necessary buildings. During the concert a collection was taken, which, as Miss Marie Tempest announced at the close of the entertainment, amounted to £300. The promoters of the concert and all who assisted in providing such an enjoyable Sunday afternoon are to be congratulated on the success of their efforts.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Monday, Jan. 19th.

SOCIAL EVENING:

At 8.30 P.M. Fellows, Members of Sections, and their friends will be received by the President, Sir StClair Thomson. At 9.30 P.M. Miss Lena Ashwell will give an Address in the Robert Barnes Hall on the Drama as a Necessity of Civilised Life. Sir T. M. Legge will give an exhibition of fifteenth century stained glass in the West Hall. The Library will be open, and various objects of interest will be exhibited. Music, light refreshments, and cigarettes.

Tuesday, Jan. 20th.

GENERAL MEETING OF FELLOWS: at 5.30 P.M.

PATHOLOGY: at 8.30 P.M.

R. A. O'Brien and Miss B. F. Runge: The Testing of Anti-dysentery (Shiga) Serum.
J. A. Murray: Tar-carcinomata in Rabbit and Rat.
A. T. Glenny and C. G. Pope: Explanation of the Toxicity of Frozen Diphtheria Toxin-antitoxin Mixtures.
C. C. Okell and H. J. Parish: Results of some Further Dick (scarlet fever) Tests.

Wednesday, Jan. 21st.

HISTORY OF MEDICINE: at 5 P.M., at the Wellcome Historical Medical Museum, 54A, Wigmore-street, W.

Papers:

Mr. C. J. S. Thompson: Anatomical Manikins.
Mr. Alban Doran: Ancient Bed Bottles and Uroscopy.

Exhibits:

Mr. C. J. S. Thompson: Drawings and Specimens of Uroscopic Glasses.

Thursday, Jan. 22nd.

EPIDEMIOLOGY AND STATE MEDICINE: at 5.30 P.M.

Paper:

Dr. F. E. Wynne: Overcrowding and Epidemic Disease.

Friday, Jan. 23rd.

STUDY OF DISEASE IN CHILDREN: at 8.30 P.M.

Discussion:

On Pneumococcal Peritonitis, to be opened by the President, Dr. H. C. Cameron.
The following will also speak: Mr. George E. Waugh, Mr. John Fraser, and Dr. David Nabarro.

THE HUNTERIAN SOCIETY.

MONDAY, Jan. 19th.—9 P.M. (at the London Mansion House).
Mr. G. Grey Turner: Perforation of Gastric and Duodenal Ulcers and After (Hunterian Lecture).
To be followed by a Discussion.

MEDICO-LEGAL SOCIETY, 11, Chandos-street, Cavendish-square, W.

TUESDAY, Jan. 20th.—8.30 P.M. Mr. F. Ll. Jones (H.M. Coroner for Flintshire): Laws of Nations and the Health of Nations: A Survey of International Health Activities Before and After the Great War. To be followed by a Discussion.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES, 11, Chandos-street, Cavendish-square, W.

FRIDAY, Jan. 23rd.—at 8.30 P.M. President's Address: The Value of the Scientific Outlook to the Worker in Venereal Diseases.

Papers will be read by Dr. Panton and Dr. Arnold Renshaw on the Vaccine Therapy of Gonococcal Infections. A Discussion will follow.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn-fields, W.C.

MONDAY, Jan. 19th.—5 P.M., Sir Arthur Keith: Recent Discoveries of Fossil Man. (Hunterian Lectures.)

WEDNESDAY.—5 P.M., Lecture II.

FRIDAY.—5 P.M., Lecture III.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Jan. 19th, to SATURDAY, Jan. 24th.—WEST LECTURE HALL, Royal Society of Medicine, 1, Wimpole-street. Lecture arranged by the Fellowship of Medicine, and open to all members of the profession. At 5.30 P.M. Tuesday, Jan. 20th, Sir Arbuthnot Lane, Bt.: The Treatment of Fractures.—WEST END HOSPITAL FOR NERVOUS DISEASE, 73, Welbeck-street, W. Intensive course in the Diagnosis and Treatment of Common Diseases of the Nervous System. Daily, at 5 P.M., Lectures, including clinical demonstrations upon selected cases.—BETHLEM ROYAL HOSPITAL, St. George's Fields, S.E. Tuesday and Saturday, at 11 A.M., Lecture-Demonstrations by Dr. Porter Phillips and Dr. Thomas Beaton.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, Jan. 19th.—12 noon, Mr. Simmonds: Applied Anatomy and Fractures. 2 P.M., Mr. Addison: Surgical Wards. 2 P.M., Dr. Scott Pinchin: Medical Out-patients.

TUESDAY.—11 A.M., Mr. Endean: Venereal Diseases. 12 noon, Dr. Burrell: Chest Cases. 2 P.M., Mr. Sinclair: Surgical Out-patients.

WEDNESDAY.—12.15 P.M., Dr. Burnford: Medical Pathology. 2 P.M., Mr. Tyrrell Gray: Operations. 2.30 P.M., Mr. Donald Armour: Surgical Wards.

THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Dept. 11 A.M., Sir Henry Simson: Gynecological Wards. 2 P.M., Mr. MacDonald: Genito-Urinary Dept.

FRIDAY.—11 A.M., Dr. McDougal: Electrical Dept. 12 noon, Surgical Registrar: Surgical Pathology. 2 P.M., Mr. Vlasto: Throat, Nose, and Ear Dept.

SATURDAY.—9.30 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10 A.M., Mr. Banks-Davis: Operations on Throat, Nose, and Ear.

Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

TUESDAY, Jan. 20th.—4.30 P.M., Dr. J. Metcalfe: The X-Ray Examination of Chest Diseases (lantern).

FRIDAY.—4.30 P.M., Mr. H. W. Carson: Prostatectomy: Its Indications and Contra-indications.

Daily, In-patient and Out-patient Cliniques, Operations, Cliniques in Special Departments, &c.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, Jan. 22nd.—4 P.M., Dr. Frew: Tonsils and Adenoids.

ST. JOHN'S HOSPITAL, 49, Leicester-square, W.C.

TUESDAY, Jan. 20th.—5 P.M., Dr. H. W. Barber: The Erythrodermas.

THURSDAY.—5 P.M., Dr. Knowsley Sibley: Lupus Erythematosus.

ROYAL DENTAL HOSPITAL OF LONDON POST-GRADUATE LECTURES.

FRIDAY, Jan. 23rd.—5 P.M., Mr. J. G. Turner: Fundamental Facts of Dead Teeth and Methods Employed in Treatment.

UNIVERSITY OF LIVERPOOL POST-GRADUATE LECTURES. (At 3.30 P.M.)

MONDAY, Jan. 19th.—(At the Shaw-street Hospital.) Dr. Leith Murray: Diagnosis and Treatment of Salpingitis.

Notes, Comments, and Abstracts.

MORTALITY FROM MOTOR-TRAFFIC: ITS CAUSES AND PREVENTION.

BY R. T. WILLIAMSON, M.D., F.R.C.P. LOND.,
CONSULTING PHYSICIAN, MANCHESTER ROYAL INFIRMARY.

THE mortality caused by motor vehicles now forms an important chapter in forensic and State medicine, and deserves much greater attention than it has hitherto received. In England and Wales the deaths caused by motor vehicles have greatly increased in number during the last 12 years. In the reports of the Registrar-General we find that the total number of accidental deaths from (1) "railways," (2) "other vehicles mechanically propelled," and (3) "horse-drawn vehicles and horses" has increased from 2140 in 1911 to 3224 in 1923. Whilst the deaths in Groups 1 and 3 have diminished in number, those caused by "vehicles mechanically propelled" (Group 2) have increased from 741 in 1911 to 2151 in 1923, and are now three times more numerous than those in Groups 1 and 3 combined. The "vehicles mechanically propelled" are chiefly motor-cars, motor-vans, motor-cabs, motor-omnibuses, motor-cycles, and electric tramcars. Considered in detail, the following table of figures, taken from the Registrar-General's reports, shows the number of fatal accidents caused by various forms of motor vehicles in the three years 1911, 1912, and 1913, and in the three years 1921, 1922, 1923 (in England and Wales).

Table showing Number of Fatal Accidents Caused by Various Forms of Motor Vehicles.

Year ..	1911	1912	1913	1921	1922	1923
Motor-car ..	286	377	455	695	751	834
Motor-van and lorry ..	69	81	132	499	551	563
Electric tramcar ..	52	39	41	55	77	80
Motor-cab ..	95	74	73	85	51	50
Motor-omnibus ..	121	192	220	133	166	219
Motor char-a-banc, coach, &c. ..				38	23	44
Motor-cycles ..	31	66	101	226	214	296
Motor collisions ..				130	118	162

The fatal accidents from bicycles and tricycles have not increased in the periods mentioned.

Thus the statistics show that the increase in the number of fatal accidents has been caused chiefly by motor-cars, motor-vans and lorries, and motor-cycles. In comparing the years 1911 and 1923 we see that in the latter year the fatal accidents caused by motor-cars were nearly three times more numerous, those caused by motor-vans eight times more numerous, and those caused by motor-cycles over nine times more numerous than in 1911. In addition, there are accidents (very much more numerous) from motor traffic which are not directly fatal. Even if it should be possible to prevent any further increase of this mortality (which is not likely), the total number of fatal accidents from motor traffic during the next ten years will be over 21,000 in England and Wales. And yet if from the upper windows of a high building in any large town we watch the motor traffic at a place where several streets or roads meet, we are apt to wonder, not that accidents often occur, but that they are not 100 times more common.

I.—Some Causes of Motor Accidents.

While some motor accidents are practically unavoidable, as the price we must pay—or make others pay—for the advantage or pleasure of travelling at a very high speed, there are many which ought not to occur. Some of such accidents are due to physical failings of the motor-driver. Of these, we need mention only a few; for example, marked defects of sight and hearing, liability to sudden attacks of illness of various kinds—cardiac failure, from aortic regurgitation or cardiac muscle disease, major and minor epileptic attacks, angina pectoris, rupture of an aneurysm, and internal hæmorrhage of various kinds. Motor vehicles are dangerous weapons; and those who handle them should not be suffering from ailments which might suddenly cause loss of control of the motor vehicle.

In a letter to THE LANCET about a year ago (1923, ii., 1377) I mentioned the case of a taxi-driver who consulted me, and admitted that it was no longer safe for him to drive a motor vehicle on account of the condition of his nervous system. He had a definite history of syphilis, and after careful examination I came to the conclusion that he was suffering from general paralysis of the insane at an early stage. His list of collisions with pedestrians was a long one, and some he had injured very seriously. I urged him to discontinue his occupation at once, but he was still driving a taxi-cab some months later.

Two recent examples may be given of the risk to pedestrians through the sudden illness of motor-drivers: (1) Whilst driving in a busy street the driver of a taxi-cab suddenly collapses through illness. The taxi-cab crashes over the footpath into a shop window, knocking down and seriously injuring a pedestrian on the footpath. The taxi-driver is taken to the nearest hospital, but dies before the hospital is reached.

(2) The conductor of a motor-omnibus finds that the driver fails to stop when he rings the bell. He then discovers that the driver has fallen off (through illness) and that the bus is dashing along unguided. With difficulty the bus is stopped, and the driver is afterwards found unconscious on the road.

Reckless Driving.

Accidents are occasionally due to the mental attitude of some motor-drivers, who appear to think that if pedestrians are not on the footpath, the driver is not responsible if an accident should occur. But in England pedestrians have still the right to use the road as well as the footpath.

It was formerly my lot to use taxi-cabs and hired motor-cars extensively. Many of the drivers thereof were gentlemen in the truest sense of the term. I have been greatly indebted to their services in remote parts of the country and often at late hours of the night; and the majority were careful and excellent drivers. But I had to cease to employ a few on account of what appeared to me to be reckless driving. Some drivers are incompetent on account of their temper or excitability, or because they fail to realise what a terrible weapon they have to control. Having never killed anyone, in course of time the fear of accidents becomes less and less, and an unjustifiable self-confidence may develop. The risks from taking alcohol are now fully recognised and the sequelæ are demonstrated daily in our newspapers.

Many motor-cars are almost noiseless in their approach, and fatal accidents may occur because the driver fails to sound his horn or hooter. Other causes of accident are very narrow streets or footpaths, lack of warning notices at dangerous parts of the road, the playing of children in the streets, dazzling headlights at night, and so forth.

II.—Prevention of Fatal Accidents.

After this brief survey of some of the causes of fatal accidents we are faced with the question—What can be done to diminish this mortality? Better mechanical construction may in the future very slightly diminish the number of fatal accidents; but so long as motor vehicles dash along at the high speeds which are now so common many accidents are unavoidable, since it is often impossible to check the speed suddenly. Those who will be responsible for the future regulation of motor traffic will have to consider if it is desirable to diminish the speed limit with the object of possibly saving some of the 2400 who are now being sacrificed yearly; or if the sacrifice of these lives is a fair price for the advantages or pleasures of very rapid transit. The maximum speed limit of motor-bicycles appears to be deserving of special attention, and pillion-riding should be forbidden. In view of the rapid increase of the number of motor vehicles, it will soon be necessary either to restrict their number or to construct special roads for them in our largest towns.

Medical Examination of Motor-Drivers.

The question which especially deserves the attention of the medical profession at present is the medical examination of drivers of motor vehicles. Is it not most desirable that they should be required to present a medical certificate that their sight and hearing are not too defective, and that they are not suffering from any ailment which might render them suddenly unable to control their vehicles? Medical examinations are required for the army, the teaching profession, and numerous occupations, for various reasons; and surely it is desirable for those who have to control such a dangerous weapon as a motor vehicle—when sudden loss of control thereof may mean the death of a human being. Most motor-drivers would be quite willing to take all risks as regards their own lives; but it is not fair that the lives of pedestrians, and of those who travel in motor vehicles should be endangered. Medical examinations would, of course, have to be repeated periodically. If such examinations should ever be made compulsory, it is to be hoped that the payment for the certificate would, in the first place, be required from the motor-driver and not from the employer. This would increase the value of the examination as a means of impressing caution. Motor-drivers should abstain from alcohol during their hours of duty, and should be required to produce a certificate that they are temperate as regards alcohol (if not total abstainers).

The Sense of Responsibility.

In the newspapers we read of another "fatal motor accident"; but we read nothing of the prolonged mental anguish, of the distress and sorrow, caused to the relatives

of those killed. We read nothing of the mental distress suffered by the driver of the motor vehicle which has caused the fatal accident, or of the anguish of the owner of the vehicle. But these cases are very numerous and the writer has met with many distressing instances. Some motor-drivers consider such questions. Some do not. Too often they are considered first after a fatal accident has occurred. Something is needed to increase the sense of responsibility—some psychological stimulus. A fine might do this. It usually takes two to make an accident when a pedestrian is killed by a motor vehicle; and it is often impossible to say how much blame should be attached to the pedestrian and how much to the motor-driver. Often neither is quite blameless. But frequently all the blame is attached to the pedestrian and none to the motor-driver. The pedestrian pays for his (?) failing with his life and the motor-driver is very often exonerated from all blame. If motor-drivers were fined for every fatal accident, whether blame could be attached to them or to those killed, this would, of course, be regarded as an unjust rule by many; but it would tend to diminish fatal accidents, and to increase the sense of responsibility. Such fines might be handed over as contributions to the needy hospitals which have to treat so many victims of motor accidents free of charge.

The Sins of the Pedestrian.

Unquestionably, in some cases the pedestrian is chiefly at fault. It is astonishing to meet, in the centre of London, men who are quite blind and alone—men who daily traverse some of the busiest streets and have to be led across the streets by kind passers-by. Many accidents happen to pedestrians because they are absent-minded, or absorbed in thought, and sometimes pedestrians are definitely reckless. Pedestrians should use the same caution in stepping off the footpath as they would use in crossing a railway line. Those who have marked defects of sight or hearing, those who are partially paralysed or ataxic, those who are liable to sudden attacks of illness (minor or major epilepsy, cardiac failure, &c.), and the aged and feeble should not walk alone in roads or streets through which motor vehicles frequently pass. With the steady increase of motor traffic, it may soon become necessary, in the busy parts of large towns, to permit pedestrians to cross the streets only at definite points, controlled by the police. Newspapers might give much assistance by publishing fuller details of motor accidents. To many it will appear that, in the past, coroners and magistrates have often failed in their duty to the public with respect to motor accidents.

The preceding remarks may be considered by some readers as suggestions for meddlesome and unnecessary interference with motor traffic; but if such readers should later have the misfortune to kill a pedestrian by their motor vehicles, they will then probably think otherwise, even if they themselves should be blameless as regards the accident.

HEALTH CONDITIONS IN BARBADOS.

A REPORT prepared by Mr. W. E. Jackson, C.M.G., Acting Governor, and dated Sept. 10th, 1924, has been received at the Colonial Office and presented to Parliament. It states that the population on Dec. 31st, 1923, was estimated to be 158,146, but as this estimate depends on emigration and immigration figures, which experience has shown to be often seriously inaccurate, not much reliance can be placed upon it. According to the census of 1921 the number of whites was 10,249, mixed 34,216, and blacks 111,677. Owing to emigration the population has declined steadily during the last two decades, though its numbers are still considerable for so small an area—940 to the square mile. Since the opening of the Panama Canal the habit of emigration has taken firm hold among the younger and more enterprising sections of the people, though it has never again reached the proportions of the Panama Canal construction period. Emigration to the United States has in recent times been the most popular, and during 1923 showed a steadily increasing tendency, over 2000 persons having left for New York. The effect of the constant withdrawal of so large a number of the younger and more vigorous members of the community, especially the younger men, is beginning to make itself felt. The birth-rate during the year was 37.44 per 1000 and the death-rate 37.11. The percentage of illegitimate births was 70.1. Up to the present there has been no registration of the causes of death in this colony, so that it is impossible to form a confident opinion as to the true causes of the unfortunately high death-rate. Ages are, however, recorded in burial certificates, and indicate that the largest factor is the deplorably high rate of infant mortality. The number of infant deaths per 1000 births during the last five years has been: 1919, 352; 1920, 220; 1921, 401; 1922, 187; 1923, 371. The causes of this high mortality are a subject of controversy, but it is generally admitted that improper and inadequate feeding is very largely responsible.

According to the census of 1921, the disproportion between males and females of the fertile ages was very great, the number of males between 15 and 50 years of age being 26,864 and the number of females 49,531. So grave a disproportion can scarcely fail to have marked social effects, and it seems probable that it must be a factor contributory towards the high rate of infant mortality. In the absence of accurate mortality statistics, however, it is impossible to speak with confidence. It is satisfactory to be able to report that an Act providing for the registration of causes of death has now been placed on the Statute Book, and will shortly be put into effect.

Epidemic Disease.

It is a fact that Barbados enjoys natural and climatic advantages from a health standpoint, such as can scarcely be found in any other tropical place. Malaria is unknown, there are no extremes of heat or cold, the soil is well drained, and the water-supply unexceptionable; it is, moreover, constantly swept by the trade winds. In these circumstances it is an unusually healthy place of residence for all who are able to secure for themselves reasonable freedom from insanitary surroundings. The diseases of insanitation, however—viz., enteric fever and dysentery—are unfortunately common. The number of cases of enteric fever notified during the last five years has been: 1919, 508; 1920, 1012; 1921, 3070; 1922, 1084; 1923, 735. The serious epidemic of 1921 fortunately subsided to some extent during 1922, but the conditions favouring the spread of the disease still remain. The ordinary type of enteric fever encountered is of a mild character. Proposals for a comprehensive review of the system of public health organisation have been placed before the legislature. The question is one which is full of more than usual difficulty, owing to the density of population and existence of vested rights, but the high and fluctuating death-rate, combined with the undue prevalence of enteric fever, indicates unmistakably that improved sanitary methods are an urgent need. Apart from the conditions above referred to, the island is exceptionally healthy and remarkably free from epidemic disease. A venereal disease clinic established at the General Hospital in 1922 has been attended by steadily increasing numbers. Subsidiary clinics in other parts of the island are much needed. The treatment of inmates of the Leper Asylum with ethyl esters of chaulmoogra oil has been continued with very hopeful results in a number of less advanced cases. It is anticipated that it may be possible to discharge some of the inmates so treated during the current year. The colony is, on the whole, well provided with curative and remedial institutions.

Climate.

Barbados is by its natural and climatic conditions the healthiest of all the West Indian Islands, and is much patronised by residents in neighbouring colonies as a health resort. The anopheles mosquito is not found in the island. This is a somewhat curious fact, since it is certain that they must be imported not infrequently in vessels which, in many cases, lie in the "carenage" or inner harbour for considerable periods on arrival from places where they are prevalent. The conditions, however, are evidently unfavourable to their breeding ashore. The hot and rainy season lasts from the beginning of June to the beginning of November. The island gets the full benefit of the north-east trade winds, and between November and May the night temperature sometimes falls as low as 64° F. For the greater part of the year the temperature is delightfully equable, and the heat is seldom oppressive. Few places, indeed, enjoy a more pleasant climate. The winter months are regarded as the tourist season.

ARGENTINE LEGISLATION WITH REGARD TO ABORTION.

Dr. Jose C. Belbey, director of the practical work of legal psychiatry at Buenos Aires, draws attention in *La Semana Médica* of Oct. 2nd, 1924, to what he holds to be certain defects and contradictions in the Argentine code. (1) The penalties for abortion are greater than those for infanticide, a manifest injustice. (2) The law permits abortion in the case of a lunatic or idiot with the consent of the legal representative of the woman but not in the case of a sane woman who has been violated; he considers that this should be recognised as legal. (3) He approves of the provision which makes a mere attempt by the woman not a legal crime on the ground that society does not suffer and that harm may be done by making a scandal public. (4) Owing to the provision in law that, if a crime is impossible it cannot be punished, it is very difficult in some cases to convict any abortionist, because unless the woman who gives the information is pregnant, the case falls to the ground. He gives an actual instance where the police were baffled by this provision of the criminal code.

That the penalties for practising abortion are lighter in the Argentine than in this country is shown by the fact that the author quotes with approval the provision which disqualifies from practice for a time double that of the imprisonment inflicted, all doctors, midwives, or pharmacists who are convicted of the crime, the previous code had disqualified them only for a term equal to that of their imprisonment. In this country the removal of the name from the Register permanently, though not enacted by statute, is carried out by the General Medical Council as a matter of course after conviction.

THE WORLD'S GREATEST NAMES.

We have received from Fort Dunlop, because "it is thought that this item of news may interest the readers of your journal," a note to the effect that the following names—Luther Burbank, Thomas A. Edison, and John Burroughs—are to be engraved on the façade of the offices and laboratories in Dearborn. The idea of Mr. Henry Ford, to whom the premises belong, has been to commemorate on his buildings the world's greatest people, and we learn that the first attempt to ascertain their identity resulted in the following list of 18 names in addition to those selected: Darwin, Devinci (sic), Fulton, Bell, Wright, Diesel, Curie, Newton, Pasteur, Ampere, Franklin, Whitney, Marconi, Kirby, Faraday, Otto, Dunlop, and Galileo. The buildings are Mr. Ford's and he can decorate them as he likes, but if he can make the educated world believe that—say—Galileo, Newton, Pasteur, Darwin, and Marconi ought to give place to a couple of field-naturalists and the inventor of the megaphone, he will be a very persuasive person. Probably he is.

THE ANTISEPTIC VALUE OF TOOTH PASTES.

To the Editor of THE LANCET.

SIR,—In your issue of Dec. 13th, 1924, p. 1266, you reviewed a paper by Mr. A. E. Parkes and Mr. A. A. Maddy, which appeared in the *Pharmaceutical Journal*, Nov. 8th, p. 563. In the course of your review it is stated: "The pastes were investigated for their antiseptic properties and the results were to show that in practically all cases the claims made by the makers are grossly exaggerated." This is surely not in accordance with the facts. Actually, in the original paper, the authors state: "With respect to the samples examined, an inspection of the literature and advertisements revealed the fact that in only one instance was any mention made of the antiseptic strength of the paste, and this was found to be substantially correct." The italics are ours, and we feel that you will wish to correct a statement which is as unjust in its condemnations as it is incorrect in fact.

In the absence of definite reference to any particular makers scathing criticism such as that in your review reflects alike on all manufacturers, and we would ask your permission to state in these columns that for some years past we have claimed a definite phenol coefficient for the tooth paste of our manufacture. Each batch of Euthymol Tooth Paste is required to show a *minimum* phenol efficiency of 0.14 when tested on the *B. typhosus*, which coefficient is not materially reduced by the presence of saliva and organic matter such as is normally present in the mouth. Moreover, independent bacteriologists have found that a 20 per cent. dilution of this paste is fatal to the *B. acidophilus odontolyticus* and the *Bacillus mesentericus*, within the space of thirty seconds—a fact which is in striking contrast to the statement in your review that "As tooth paste remains in contact with the teeth for a few seconds only, it seems clear that the paste even in an undiluted state can have little, if any, effect upon the germs of the mouth."

We are, Sir, yours faithfully,

London, W. 1, Jan. 8th, 1925.

PARKE, DAVIS & CO.

*** The number of different makes of tooth paste on the market probably runs into four figures; the authors of the paper reported on 12 only. Their findings fully justify the general conclusion that the claims made by makers are exaggerated, but the condemnation obviously does not apply—nor does our abstract suggest that it does—to the few cases in which reasonable claims are made. None of the pastes examined was identified by name, and the only evidence that the paste to which attention is now drawn by the makers of it was examined was in the authors' preliminary remarks to the effect that they selected the most popular. Admittedly this product passes the test of popularity—and deservedly so.—ED. L.

Mrs. F. G.—It is not, we believe, the practice of physicians here to send their neurotic patients to British Columbia with the assurance that they will there get the necessary rest for their nerves.

An Address

ON

ACUTE HÆMATEMESIS AND MELÆNA.

*Delivered at the Manchester Clinical Society on
Jan. 21st, 1925,*

By JAMES SHERREN, C.B.E., F.R.C.S. ENG.,
SURGEON TO THE LONDON HOSPITAL, ETC.

As this is a clinical society I have not hesitated to use two symptoms as the title for my address and to review them in the light of my own personal experience, only supplementing this by hospital records in a few instances. I am using the terms in their generally accepted meanings, hæmatemesis—the vomiting of blood, and melæna—the passage of altered blood per rectum. This use of the latter is modern, but its employment in this way is now sanctioned by usage, and it is forgotten that it formerly designated a disease characterised by evacuation from the bowel and vomiting of dark bloody matter. Comparatively recently it implied the ejection of black matter from either stomach, bowel, or both. The term acute is used to signify the sudden onset of severe hæmorrhage, and I am dealing only with those cases in which hæmorrhage is the symptom for which aid is sought. I am not considering those in which streaks of blood in small amounts are vomited, occult blood discovered in the fæces, or large quantities of unaltered blood passed from a simple or malignant growth of the colon or rectum.

A CONDITION AMENABLE TO CLINICAL STUDY.

Bleeding from the gastro-intestinal tract is an eminently suitable subject for clinical study. It owns many causes, some of which are directly amenable to surgical treatment and are curable. In some recovery is usual without operative interference and with very little risk to life; in others the outlook is grave unless operation is carried out at the earliest opportune time. The operative treatment required may be as diverse as partial gastrectomy or omentopexy, and it therefore opens up a survey of almost the whole range of abdominal surgery. The question of immediate treatment is one that we have frequently to face. Nothing is more alarming to patient and friends than a visible loss of blood. Our medical colleagues, knowing that the control of hæmorrhage is the province of the surgeon, call us in, and we need to have reasoned answers for our delay or for our plea for operation.

Recently considerable interest has been aroused in this condition, and, as you may remember, there has been a joint discussion on the subject at the Royal Society of Medicine,¹ a lecture there by Gustave Monod² on hæmatemesis “without lesions,” and a short paper on its surgical treatment by my friend and colleague, Mr. A. J. Walton.³ I was unable to attend the discussion, but views differing so much from my own appear to have been expressed at that meeting and given in the papers that I started to review my clinical evidence. I am fortunate in having an almost complete record of the after-history of the patients upon whom I have carried out abdominal operations, as, from the very first, I have had a regular follow-through system and thus am able to find out results in a very short time. In point of individual experience as opposed to collected statistics, judging from other figures, I have had an exceptional number of cases; they are certainly sufficient to enable a definite opinion to be given.

Hæmorrhage presupposes a breach of surface; I am not convinced that oozing of blood from a mucous membrane can be the cause of serious bleeding. In the early days of gastric surgery I operated upon patients during the stage of acute hæmorrhage, and in a certain group was unable to discover any lesion. In all, however, that then came to post-mortem examination and in all that have occurred later definite gastric erosions or acute ulcers were found. I am aware that there are those who believe in this possibility. Your President,⁴ Mr. A. H. Burgess, in his contribution to the joint discussion previously mentioned, has recorded two cases in which at post-mortem examination no gross lesion could be found to account for the hæmorrhage. Monod mentioned three recent cases in his paper, in whom no lesion was discovered at operation, from which all recovered. But as it is manifestly impossible exhaustively to examine the mucous membrane of the stomach through any safe ante-mortem incision these are not convincing. It has sometimes only been possible to find the lesion after death by stretching the stomach and holding it up to a strong light.

The matter is not of mere academic interest, as I believe that many of these patients may develop chronic ulcers in later life. I dealt with the subject of hæmatemesis from acute ulceration of the stomach very fully in a paper published last year⁵ based on 63 cases treated by operation.

TWO CLINICAL GROUPS OF CASES.

The cases I wish to consider now fall into two clinical groups—(1) in which the patient has been in perfect health and has had no previous digestive trouble requiring medical aid, and (2) those with a preceding history of digestive disturbance.

1. This is the most difficult to deal with both from the point of view of diagnosis and of treatment. There are two classes of case, the typical “gastric ulcer” of my student days much less common than formerly, the anæmic woman of 18 to 25, and the adult of either sex who without warning vomits a large quantity of blood or has a fainting attack and passes it altered per rectum. Both are of extreme importance, but in the latter the problem is one to which the answer is urgently necessary in view of the serious risk of overlooking a lesion of grave import, for carcinoma of the stomach may herald its presence by this means and certain cases of chronic ulcer of the stomach or duodenum.

2. In the second group the hæmorrhage is a complication, usually a very grave one, which follows months or years of abdominal ill-health and needs much less discussion from the point of view of diagnosis and treatment. I have been surprised to read that hæmorrhage from a chronic ulcer was not looked upon as a particularly dangerous complication, and that both surgeons and physicians of wide experience had never seen a death from hæmorrhage from this cause. In considering the risk of delay in the surgical treatment of these cases it is useless to argue from figures in which both acute and chronic ulcers are taken together, as the death-rate in the former is very low under efficient medical treatment, I have always considered it as a very grave complication, and have had patients die of hæmorrhage while awaiting operation, or because it was not undertaken at the most opportune time. In addition four patients of mine who had had hæmatemesis died as the result of perforation while awaiting operation. The last occurred just before Christmas.

A patient, male, aged 42, was under my care at the London Hospital 18 months previously with a chronic gastric ulcer. He had a very septic mouth and refused treatment, both dental and abdominal, and left hospital. He remained in good digestive health till two days before admission, when he had slight epigastric pain followed in 36 hours by profuse hæmatemesis for which he was sent

⁵ THE LANCET, 1924, i., 477.

up by his medical man. His condition was extremely bad, but I considered that the risk of delay was less than the risk of operating, as his mouth was in a condition only to be described as appalling. However, after being in bed for 13 days and six days after all hæmorrhage had ceased, he suddenly perforated at 4 A.M. and died in spite of immediate operation.

It is cases such as these that makes me consider hæmatemesis from a chronic ulcer very seriously.

I have been under the impression as the result of my personal experience that hæmatemesis is much less common than formerly and that the age and sex incidence have changed. To test this I asked my first assistant, Mr. G. P. B. Huddy, to take two years separated by an interval of ten and ascertain the admissions both to medical and surgical wards of all cases of acute hæmatemesis. In the year 1913, 81 cases were admitted to hospital for this cause; 45 were female. In 1923, 48 cases, only 16 female. This, although the total admissions of patients with gastric and duodenal ulcers had risen from 224 in the former year with 59 women to 348 in the latter with 74 women. The age-incidence has also changed. In 1913 more than half the cases (41) were under the age of 35, and 14 between 20-25. In 1923 only four occurred in this quinquennium, and 14 before 35. I believe this diminution to be due to two causes. In the first group to better care of the mouth and nasopharynx and the better treatment of abdominal infections, in the second to earlier operation on chronic ulcer preventing the later onset of hæmorrhage. They show that preventive surgery is as important to the individual as preventive medicine.

CASES WITHOUT PREVIOUS DIGESTIVE TROUBLE.

The type in the first group was formerly the young anæmic woman, but this sex-incidence is becoming much less common, and it is now just as frequently met with in the young male. Acute hæmatemesis of this nature is accompanied by much collapse, and the immediate treatment is an adequate dose of morphia and warmth. The less that is done beyond this the better. I have never seen the advantage of withholding water by the mouth; it can have no effect on the bleeding, and thirst is more easily controlled and with less exposure than by rectal infusion. Ice to suck and an ice-bag applied to the epigastrium are practices that have nothing whatever to recommend them. In this type of case I believe that operation is never indicated. The possibility of the bleeding coming from an ulcer that can be recognised, or if recognised adequately dealt with, is very small indeed. The risk of exploration is much greater than that of efficient non-operative treatment.

Acute Ulcer.

Gastro-jejunostomy is still advocated in certain of these cases, when the bleeding is severe and the patient in a condition of the gravest danger.⁶ If the bleeding is the result of acute ulceration with a recent infection of the stomach, this operation only involves additional risks, and if the hæmorrhage is coming from an eroded artery I fail to see how it is to be stopped by a gastro-jejunostomy, which must of necessity be performed without any reference to the site of the lesion. Your President and myself, among others, have both recorded cases in which hæmorrhage continued unchecked by gastro-jejunostomy and lead to the death of the patient. In my opinion, under no circumstances should operation be carried out at the time of the hæmatemesis. If the bleeding recurs it is good treatment to wash out the stomach gently with warm water to which one drachm of soda bicarbonate to the pint has been added, with the possible addition of adrenalin. I think there is too much tendency to keep these patients for an undue length of time without food. So soon as desire returns a start should be made with albumin water and then some such unirritating diet as Benger's food. It

must be but seldom that blood transfusion is called for in cases of this type. This is the immediate treatment of the patient.

So soon as possible a working diagnosis of the cause of the bleeding must be found. What are the possibilities? By far the commonest is acute ulceration of the stomach due to infection; such causes as the vomiting of blood swallowed from epistaxis need not detain us, but we must be on the alert for rarer conditions, such as simple tumours of the stomach and disease of the spleen, and very exceptionally indeed, blood diseases. I have been called to two cases of hæmatemesis in which abdominal examination revealed an enlarged spleen and to one in which operation later discovered the cause to be an adenomatous polypus.

The whole patient must be examined, search being made for possible source of infection, particular attention being paid to oral cavity, including teeth, tonsils, naso-pharynx and ears, and lungs. Acute hæmatemesis may be a complication of early pulmonary tuberculosis, and I have been struck with the frequency with which this disease has been found in association with chronic gastric ulcer. Blood examination, not only to determine the grade of anæmia, but the presence of any of the rare blood diseases known to be associated with this condition, and to group the blood in view of possible transfusion. It is well for purposes of record and for comparison with later investigations to have test and barium meals given which may provide corroborative evidence of importance, and in the latent cases of chronic ulcer may show the lesion, and so indicate the necessity for treatment without delay.

If infective foci are found, these must be treated, the bowels regulated, and the patient kept under observation with the warning that further hæmorrhage should lead to abdominal exploration. If the investigations in any way point to abdominal disease, operation should be carried out. In those cases in which every investigation as to cause brings a negative result I am strongly of the opinion that it is safer to explore the abdomen. I believe that it is often possible to prevent further hæmorrhage and the occurrence of chronic ulceration of the stomach or the development of gall-stones later.

In the paper previously mentioned I drew attention to this matter, and lay stress on the importance of recognising these cases of acute hæmatemesis as usually due to acute ulcers, not only from the point of view of the prevention of further acute ulcers but of chronic ulcers and their later complication, carcinoma. The findings in the 63 cases explored were as follows: in 29 definite disease of the appendix was found, in 15 cholecystitis. I have been able to follow up the majority of these and proved them to be well. Since that paper was written I have operated on a further six; in one that I shall mention presently an acute ulcer was later discovered post mortem, in three the appendix was at fault, in two the gall-bladder; in these last two, as in four previously reported, a pure culture of colon bacillus was obtained from the bile.

I have had many instances of patients with chronic gastric ulcer in whom there was a very definite history of painless hæmatemesis several years before. When these cases of acute hæmatemesis were operated on at once the death-rate was high—even if nothing was done and we usually failed to find the ulcer or ulcers. Recently I was led to this procedure in the belief that a chronic ulcer was present; nothing was found on exploration, the bleeding continued, the patient died, and autopsy revealed an acute ulcer. He was a man of 39, who eight months previously had had pain after food not accompanied by vomiting. He then got quite well and remained so until four weeks before admission to hospital, when he had a similar attack which culminated in a profuse hæmatemesis on June 24th, 1924, when he was admitted to hospital. Three days later he had another hæmatemesis, and as he was not recovering I was asked to see him.

⁶ Walton, A. J.: THE LANCET, 1924, i., 477.

He was pale with a pulse of 120. In few of the past history I operated; all abdominal gans appeared normal. Stomach and duodenum were normal, gall-bladder and spleen normal. I removed his appendix, which to the naked eye was normal, and this was confirmed on microscopic examination. As is my usual practice, I returned to the examination of the stomach and duodenum after exploring the whole abdomen. I have found that in this way ulcers can be discovered which otherwise might easily be missed. The exposure of the viscus leads to a definite change in the peritoneum around the ulcer, the area being surrounded by a red stippling, which I described many years ago.⁷ At the post-mortem no thickening of peritoneum or any other external abnormality of the stomach was found. On opening the stomach a shallow circular ulcer was present, 1.5 cm. in diameter on the lesser curvature, 9.5 cm. from the pylorus, with a perforation leading directly into a branch of the coronary artery.

Acute ulcers may become chronic under certain conditions, but in women, particularly those with gastric ptosis, there may be recurrent acute ulcers with repeated attacks of hæmatemesis. This is the type of case that frequently develops an hour-glass stomach, and in many, at the time of operation, the ulcers which produced it have healed. I have had the opportunity of following cases from the acute ulcer stage to that of hour-glass stomach on the one hand, and to chronic gastric ulcer and carcinoma on the other.

Causes other than Acute Ulcer.

As I have said previously, the usual cause for a painless acute hæmatemesis is an acute ulcer, but in addition to the causes I have mentioned, it may be the first prominent symptom in cirrhosis of the liver.

Hepatic Cirrhosis.—I have seen it stated that cirrhosis of liver is one of the commonest and most important causes of acute hæmatemesis.⁸ This has not been my experience; I look on it as one of the rare causes. I have had experience of three cases, one of which came under my care last year. In order to see if this was borne out by the general hospital figures, I again asked the help of my first assistant. In the two selected years there was no admission for hæmatemesis diagnosed as due to this cause or in which the diagnosis was arrived at later. On investigating the P.M. reports it was discovered that in a patient who was admitted with hæmatemesis and died almost immediately, marked cirrhosis of liver was present with acute gastric ulcers and acute endocarditis. It is possible that the acute ulcers were due to infection, and the hæmatemesis to this and not to the cirrhosis. I believe omentopexy is indicated in the hæmatemesis due to cirrhosis of the liver.

Gastric Carcinoma.—I need say little about the treatment of acute hæmatemesis due to carcinoma of the stomach. The knowledge that such a condition may be the cause in adults is enough.

Splenic Enlargement.—Acute painless hæmatemesis is by no means an infrequent complication in certain cases of enlarged spleen and does not necessarily indicate concomitant cirrhosis of the liver. I have removed the spleen in eight cases on account of an acute hæmatemesis that first brought the patient under observation, and three of these patients I was asked to see as "gastric ulcer." One of them had been in hospital three times previously with hæmatemesis.

The following are my figures supplementing those I gave in 1918⁹: I have carried out splenectomy in 25 cases of splenic anæmia (I am using this term to include Banti's disease); among these, 8 were undertaken for hæmatemesis; the liver was cirrhotic to naked-eye examination in 4 only; in the whole series it was cirrhotic in 10. There was only one death among the 25, a boy of 14, in whom there was doubt

of the diagnosis and which was probably primary liver cirrhosis. I have recorded it elsewhere.⁹ Of the eight cases operated upon because of their hæmatemesis all those in whom the liver was normal at the time of operation are quite well and have had no further hæmatemesis—11 years, 8 years 9 months, 5 years 3 months, and 18 months later. Of the 16 cases in which there was no hæmorrhage previously to operation all those without cirrhosis of liver have had no hæmorrhage and are quite well. Of those with cirrhosis one has had melæna on one occasion, but is now well. Among the four cases operated on for hæmorrhage in whom cirrhosis of liver was present two died, one 18 months later from a further hæmorrhage, and one, with very advanced cirrhosis, of exhaustion after being tapped many times. The following are brief notes of these cases.

A woman of 21, who had had an enlarged spleen for 14 years, and in the year before I operated had had three profuse hæmorrhages. She had ascites and had been tapped on one occasion, 17 pints being withdrawn. After operation she regained and remained in perfect health for 18 months, when she died after a very profuse hæmorrhage. A man of 35, who noticed swelling of his abdomen and seven months later vomited blood. He was admitted to hospital; 14 pints of fluid were withdrawn by tapping, and four days later 15 pints. I was asked to see him. I operated, the liver was large and cirrhotic, and I removed a spleen which weighed 2 lb. 5 oz. He stood the operation well, but had to be tapped three weeks later and then at 14 daily intervals. He died of exhaustion two months after operation.

Duncan Wood¹⁰ has recorded two cases with full post-mortem reports in which the origin of the fatal hæmatemesis was from rupture of an œsophageal varix in one case, an enlarged vasa brevia in another. In both cirrhosis of liver was present at the time of the splenectomy, but even when this is marked patients remain well over long periods of time. For example, in 1914 I operated on a boy of 12 who had typical Banti's disease with ascites, and removed his spleen. The liver was large and cirrhotic. He has remained in perfect health, and I last saw him in December, 1924. I look on removal of the spleen in these conditions as a most satisfactory operation. If undertaken before the onset of cirrhosis of liver the word cure can justifiably be used. Even after the onset of cirrhosis the majority of patients remain well, but hæmorrhage may recur and prove fatal.

Melæna.

Melæna may similarly be the first symptom which brings the patient to the medical man. It may appear in the midst of perfect health and in this type is found almost exclusively in men. The immediate treatment is the same as in acute hæmatemesis. Melæna occurs much more often in the early hours of the morning than does hæmatemesis; a very common history is that the patient gets up about 2 A.M., goes to the lavatory and faints. While acute ulcers of the duodenum do undoubtedly occur they are much more rare than acute gastric ulcers and, on the other hand, a chronic duodenal ulcer more frequently, but still very rarely, remains latent, and does not give rise to symptoms until bleeding occurs.

Immediate treatment should be followed by thorough investigation, and, just as in hæmatemesis, exploration undertaken if no external cause is found with a view to treating the lesion, if it can be demonstrated, and removing its cause. All of us must have known of patients operated upon for painless melæna and gastro-jejunostomy carried out, no lesion having been discovered, and the attacks have recurred as before. I should like again to say that I consider gastro-jejunostomy should never be performed in the absence of a demonstrable lesion. I say this knowing full well that I have operated and been unable to discover an ulcer, only to find it years later and to have it found later by others.

In thus separating melæna and hæmatemesis I do not want it to be understood that hæmatemesis does

⁷ Annals of Surgery, March, 1915, p. 380.

⁸ Index of Differential Diagnosis, p. 272.

⁹ Annals of Surgery, October, 1918, lxxviii., 379.

¹⁰ British Journal of Surgery, January, 1924, p. 587.

not occur with duodenal ulcer; it does, and very profusely, but as a rule melæna is the more marked. Similarly in chronic gastric ulcer it is very rarely indeed that melæna is present without hæmatemesis; when this happens it is usually in cases with hour-glass stomach.

CASES WITH PREVIOUS HISTORY OF INDIGESTION.

To turn now to those cases of hæmatemesis and melæna in which a chronic ulcer is diagnosed on a preceding history of long-continued attacks of indigestion. Here operation should be carried out as soon as the condition of the patient will admit. I am not an advocate of "immediate" operation, meaning thereby intervention during the period of hæmorrhage. In cases of bleeding from a chronic ulcer there is often a period after the first vomiting or melæna in which it is possible to operate; if this is not seized upon other and fatal bleeding may occur as in secondary hæmorrhage which it so much resembles. This is what I meant by operation at an opportune time, a view put forward on my behalf by my colleague, Dr. Robert Hutchison, at the before-mentioned discussion.

Bleeding from a chronic ulcer may be due to the rupture of a small aneurysm, or much more commonly to an acute infection spreading into the vessel. There are two great dangers—we are dealing with a hæmorrhage comparable to secondary hæmorrhage that brooks no delay, and also there is the danger that I consider is a very great one of coincident perforation, due to acute change in the ulcer. My practice has been to operate as soon as possible after the shock of the first hæmorrhage; this is usually in about 36 hours, plenty of fluid being given meanwhile, and, if necessary, a blood transfusion. It is essential to deal *directly* with the ulcer. If in the stomach, I usually tie the vessels on either side, destroy the ulcer with the cautery, and do a posterior gastro-jejunostomy to its cardiac side, but partial gastrectomy may be necessary; in the duodenum, posterior gastro-jejunostomy after the destruction of the ulcer with the cautery, taking care in suturing not to narrow the pylorus.

The immediate results of treatment are better in duodenal ulcer than in gastric, the remote are not so favourable. Up to the end of 1922 I had operated on 73 cases of chronic duodenal ulcer for acute hæmorrhage with 4 deaths, 82 cases of acute hæmorrhage from a chronic gastric ulcer with 7 deaths. It will be remembered that the death-rate in the treatment of uncomplicated cases of gastric ulcer is higher than that of duodenal. Of the 69 survivors of the cases of duodenal ulcer 50 have remained well more than two years after operation, 27 for more than six years, 14 for more than ten. Thirteen had recurrence of bleeding, and of these I wish to speak more fully later, in dealing with post-operative bleeding, and 6 were lost sight of before two years had elapsed. Of the 76 gastric survivors, 69 are quite well over two years, 41 over six years, 12 over ten years—really excellent results. In one remarkable case I was able to get a post-mortem 30 months later.

On June 6th, 1919, a male, aged 44, was admitted to the London Hospital with acute hæmatemesis which recurred four days later. He gave a typical chronic gastric history extending over six years. At the operation on June 24th, I found a large indurated ulcer in the centre of the lesser curvature and have a note that had his condition admitted I should have carried out partial gastrectomy. I tied the vessels on both sides of the ulcer and did a posterior gastro-jejunostomy to its cardiac side. He remained quite well abdominally but died of pulmonary tuberculosis in December, 1921. At the post-mortem the gastro-jejunostomy opening was perfect and 4.5 cm. in diameter. The only remains of the ulcer was a faint scar on the lesser curvature.

There has been no recurrence of bleeding in any uncomplicated case. In one of my early cases, however, I had to do a lateral anastomosis later on account of occasional vomiting. He had a slight hæmatemesis a few months later which was not repeated. This is

the only case of hæmatemesis I have had after operation for chronic gastric ulcer.

Showing the uselessness of gastro-jejunostomy alone and also evidence of what I have already stated that the hæmorrhage is usually due to an acute infection is the following:—

In October, 1914, I operated on a man of 35 who had been having attacks of pain for over a year, and four days before I saw him had an acute hæmatemesis which was repeated. At operation I found a small chronic ulcer on the lesser curvature near the pylorus, treated the ulcer in the usual way, and carried out posterior gastro-jejunostomy. Post-mortem revealed in addition to the chronic ulcer an acute ulcer higher on the lesser curvature with a small ruptured aneurysm.

This while showing the recent acute infection is, of course, fortunately very unusual, the acute infection in most cases being of the original chronic ulcer.

POST-OPERATIVE HÆMATEMESIS.

We now come to a very important group, that of post-operative hæmatemesis. This may occur after any abdominal operation, and I shall speak of it under two headings.

(1) *After Operation upon Abdominal Organs Generally.*

This is well known after operation for abdominal infection, particularly in connexion with acute appendicitis and acute cholecystitis. It is exceedingly rare, and in a number of cases a definite chronic ulcer has been found post mortem, the bleeding being due to an acute infection. In other cases acute ulcers are present of infective origin. Treatment is on the lines indicated with that of the general condition and the prognosis grave.

(2) *After Operations on the Stomach: Early Hæmorrhage.*

Nothing can be more alarming to the patient and his friends or more distressing to the surgeon than an acute hæmorrhage following gastro-jejunostomy or partial gastrectomy. All had gone well and a good prognosis given when the surgeon is recalled a few hours later to find the patient at death's door. Nothing but immediate operation is justifiable, the anastomosis must be undone and restitched. Fortunately I rarely had to do this, and since I have left off using a jejunal clamp and loosen the gastric one before putting in the anterior layer of sutures, I have never had a case of post-operative bleeding, and it must be of the greatest rarity. In any case, even before this, it was extremely rare. I will give you figures obtained from my last 100 cases of gastro-jejunostomy in which I think hæmorrhage was prevented in two, for after loosening the gastric clamp I had to secure a spurting vessel which would have caused serious bleeding and might have necessitated a second operation.

At a time when there was difficulty in obtaining what I consider the best catgut for stomach operations I had two cases of delayed hæmatemesis from too early absorption of the inner layer of sutures, both alarming, but neither fortunately fatal or of sufficient severity to require intervention. Both occurred on the fifth day after operation.

Remote Post-operative Hæmorrhage.

I now want to turn to acute hæmorrhage occurring at late periods after gastro-jejunostomy for chronic duodenal ulcer, cases with which I am afraid we are all familiar, which impress themselves on our imagination and make us think that they are more frequent than they really are. As I was writing this a patient returned to hospital who illustrates excellently points that I wish to bring out.

S. N., a male, aged 34, was sent to me on Nov. 12th, 1923, with the following history: For 14 years he had had attacks of pain late after food with free intervals. Night waking had been a feature for four years. Five weeks before I saw him

he had a severe hæmorrhage with three relapses. He was a thin man, anæmic, and in spite of his recent bleeding his test-meal was 0.16 free HCl, 58 total acidity. I operated on Nov. 30th, and found two chronic ulcers on the anterior surface of the first part of the duodenum. The gall-bladder was normal. I could not investigate his appendix owing to his condition. I destroyed the ulcers with the cautery, sutured vertically so as not to narrow the pylorus, and carried out the usual posterior gastro-jejunostomy. He had an uninterrupted convalescence, but did not show a satisfactory reduction of gastric acidity. His post-operative meal was 0.16 and 58. He was readmitted to hospital after a severe hæmatemesis on Nov. 13th last. Up to ten days before admission he was perfectly well. He then began to lose energy and to look pale. He fainted several times and passed black stools. On the day of admission he was suddenly seized with profuse hæmatemesis. He rapidly recovered under the usual treatment. His test-meal was 0.14 and 50, and his barium meal showed no abnormality. As I had not been able to remove his appendix I reoperated on Dec. 19th. The site of the ulcer was visible as two thin smooth scars; the anastomosis was perfect. I removed the appendix, which to the naked eye showed slight thickening of its tip.

The points I want to draw attention to are these. Those patients who have had hæmorrhage shortly before operation are those liable to get it again. Those cases in which there is not sufficient post-operative reduction of gastric acidity frequently have further symptoms, not necessary hæmorrhage, but those with this symptom before operation may get it after. It is only found after duodenal ulcer, and even then is a rare post-operative symptom. It is quite obvious that bleeding of this sort must come from an ulcer. My experience, as I have frequently said, is that chronic gastric and duodenal ulcers heal when gastro-jejunostomy is correctly performed, and that any later symptoms that may arise are due to fresh ulceration either in the region of the anastomosis or in the jejunum, but as I shall hope to show these ulcers may be so minute as to be undiscovered at operation.

To take first of all the cases of chronic ulcer operated upon for hæmorrhage up to two years ago. None of the gastric cases, with the exception of that just mentioned, suffered from remote post-operative bleeding even when they had been operated on for hæmatemesis; there was no difference in those treated by partial gastrectomy or gastro-jejunostomy. Eighteen cases of chronic duodenal ulcer suffered from post-operative hæmatemesis, but of those 13 had it before operation. In all these cases the bleeding was profuse, necessitating treatment in bed.

It will be obvious that the risk of remote post-operative hæmatemesis in those cases of chronic duodenal ulcer who did not suffer from it before operation is very slight, among my own cases about $\frac{1}{3}$ per cent. There are two possible sources: (1) the original ulcer, (2) fresh ulceration or erosions. I have many times made the statement that the original ulcer heals when it is of a suitable nature for treatment by gastro-jejunostomy, and in these cases, unless the ulcer is a large posterior one eroding the pancreas, healing always takes place after a gastro-jejunostomy, and my experience now extends to over 60 re-examined at a second operation or post-mortem at remote periods.

Cases with no Bleeding before Operation.

Those cases in which there was no bleeding before the operation are five in number. In all except one it came on within 18 months of operation. One patient, operated on in 1912, has had three attacks, the last a year ago; another, operated on in 1913, had attacks lasting to 1916, and has been quite well ever since, and last month I had a letter from him stating he had never been so well in his life. The third had a profuse hæmatemesis after slipping downstairs 13 months after operation, and now, 20 months later, is quite well without further trouble. None of these were explored. The fourth is the most interesting and difficult to account for.

In December, 1915, I operated on a male, aged 37, who since the age of 17 had had attacks of pain after food. I found a mass in the first part of the duodenum with a

definite anterior ulcer. I invaginated it and carried out posterior gastro-jejunostomy and removed a much thickened strictured appendix. He remained absolutely well until August, 1921, when he was camping out; he felt giddy one evening and at 5 A.M. next morning had a profuse hæmatemesis, repeated that day and the third day. He remained in bed a month and I saw him two months later. His test-meal was 0.11 and 52, much too high for a patient with a gastro-jejunostomy. I explored and found the duodenal ulcer absolutely healed and the first part of the duodenum normal but for a faint scar. There was no trace of ulceration in the jejunum or at the anastomosis. I opened the stomach and examined by sight the anastomosis and jejunum. His gall-bladder was normal. I heard seven months later that he had had another attack of an exactly similar nature.

I have quoted this case rather fully, for it stands unique among my cases in that symptoms first appeared at a period longer than two years after operation; in this instance there was nearly six years of perfect health. In one patient, a male of 40, operated on in 1911, painless hæmorrhage occurred in five months. I operated and found a true jejunal ulcer. He remained well and died of another cause nearly eight years later. We obtained a P.M. and found faint scars in duodenum and jejunum. I have post-operative test-meals in 13 out of these 18 cases; in 8 there was but little reduction; in 5 it was reduced almost to normal, in itself high after a posterior gastro-jejunostomy.

Cases of Recurrent Bleeding.

We now pass to those cases, 13 in number, which were operated on for bleeding and in which it recurred. It seems from what I have read on the subject to be assumed in many cases that this comes from the original ulcer or a recurrence. I do not believe this to be the case, not only because I have never seen it unhealed in many inspections, but because I think I have evidence to prove fresh ulceration. Of these patients one developed a definite jejunal ulcer, one an ulcer at the anastomosis, from which I removed silk. Two others were explored, one five years ago, but two years after the original operation. The duodenal ulcer had healed and there was no trace of secondary ulceration. He has remained quite well and is playing Rugby football. The other, eight and a half years ago, 22 months after his original operation, exactly the same state of affairs was found, and he remains well.

From these remarks two facts seem to emerge—one is that these post-operative hæmorrhages may result from definite chronic secondary ulcers, but usually no lesion is discoverable, and I believe it emanates from small erosions due to infection. It behoves us, therefore, to be satisfied that we have cleared up all abdominal infection. If the condition of the patient would not admit of this at the original operation and the post-operative meal shows insufficient reduction of gastric acidity, then further exploration should be carried out. In the patients reoperated on, in two I removed the appendix, which I had been unable to do on the first occasion. As far as the original operation was concerned I have been quite unable to find any constant common factor either in the position of the ulcer or in adhesions, or in the condition of other organs. As I have said on another occasion, if we knew the cause of secondary ulceration we should also know that of primary.

As these post-operative hæmorrhages occur almost entirely after gastro-jejunostomy for chronic duodenal ulcer, and we know that true jejunal ulcers also occur almost exclusively in this condition, and only found when acidity is not reduced, I look on them as small acute ulcers of this nature. In treating these cases of post-operative hæmatemesis a careful examination of teeth and naso-pharynx must be made, but lesions here should, of course, have been treated before the first operation. In cases of painless hæmatemesis, if the surgeon is satisfied that everything necessary in the abdomen was done at the previous operation, exploration should not be undertaken. In the rarer cases in which it is preceded by pain, and there is some evidence of a chronic jejunal ulcer, a thorough course of treatment directed towards reducing gastric

acidity must be carried out, and only if relapse occurs should operative treatment be advised.

Failure to Reduce Gastric Acidity.

We have yet to learn what is the cause of failure to reduce gastric acidity by gastro-jejunostomy. I am convinced that it is essential if the operation is to be permanently successful. I have been and still am working at the subject, and although we can trace the cause in certain cases, yet in others in whom a procedure in every way identical is carried out for a lesion in every way comparable, in one patient it results in a post-operative meal of, say, no free HCl and a total acidity of 20, and in another 0.1 and 50. I believe that it is in some way due to insufficient emptying of the gastric contents through the pylorus, hence the secretion of pancreatic juice is not sufficient. There is no doubt that pyloric exclusion prevents post-operative reduction, and I am sure that the most usual single cause is adhesions of gall-bladder to duodenum, interfering with the free use of the pylorus. I am convinced that for the most effective lowering of acidity it is essential that the pylorus be used as well as the new opening. Gastro-jejunostomy cannot be looked upon as purely a mechanical operation. I should like to reaffirm what I stated last year—no patient in whom the operation brought about a sufficiently lowered gastric acidity has had any post-operative symptoms whatever.

The lessons I have drawn from this small piece of clinical research seem to me to point out the great necessity for preventive treatment—to learn the cause of acute ulcers, and so prevent their occurrence, and when once they have developed so to treat the patient that they do not progress and drift into the group of recurrent ulcers or the true chronic ulcer, and then that operation on this type should not be delayed until hæmorrhage has occurred. The old adage holds: Prevention is better than cure.

PERIODIC MEDICAL EXAMINATION.

Being a portion of an Address read before the Assurance Medical Society, on Jan. 7th, 1925,

BY OTTO MAY, M.D. CAMB., M.R.C.P. LOND.,
PRINCIPAL MEDICAL OFFICER TO THE PRUDENTIAL
ASSURANCE COMPANY.

[IN opening an address on Life Offices and the Care of the Policy-holder, Dr. May said that, fundamentally, the aim of every life office, whether mutual or proprietary, must be to benefit its policy-holders by improving, as far as possible, its mortality experience. From the theoretical point of view this could be achieved along two chief lines: (1) by stringent selection at entry, including the careful assessment of impaired lives, and (2) by organising the care of policy-holders, so as to give them special facilities for the prevention and treatment of sickness, and thus help to ensure a favourable mortality.

Up to the present time British companies had concentrated their efforts almost entirely along the former line; in America, however, a good deal has also been attempted by some of the leading companies along the latter line. He suggested that the health activities of an insurance company might be classified under three headings, each of which he discussed in detail. These were (1) general health propaganda, (2) the endowment of research, and (3) the care and treatment of individual policy-holders. Dr. May summarised the activities on these lines of the Metropolitan Life Assurance Company of New York, which, he said, appeared to be the most active of all in the care of its assured. Under the third heading, an important item was the periodic medical examination of policy-holders, on which Dr. May spoke as follows:—]

The outstanding feature of the health work of the Metropolitan Life Assurance Company of New York

among ordinary policy-holders is the provision of facilities for *periodical medical examination*,¹ free of all cost to the holders. This scheme has been in existence since February, 1914, and allows the following privileges: (a) For holders of a policy of \$1000—an examination after four years, and every fourth year thereafter; (b) for holders of a policy of \$2000—after three years and every third year; (c) for holders of a policy of \$3000—after two years and every second year; (d) for holders of a policy of over \$3000—after one year and thereafter every year.

The examinations are conducted on behalf of the company by the Health Extension Institute of New York—an institution which undertakes periodical examinations for some 30 different insurance offices, as well as for employers and private individuals. It has branches throughout the States, so that policy-holders can be examined in almost any town of importance. The examination includes a routine survey by ordinary methods of the heart, lungs, abdominal organs, nervous system, nose and throat, eyes, general physique, and blood pressure, and a chemical and microscopical examination of the urine.

Nothing is said as to the provision of facilities for sputum examination, radiography, or blood examinations. Presumably, if their desirability is indicated by the routine examination, the policy-holder is referred to his own medical attendant for further investigation. The result of the periodical examination is confidential between the examiner and examinee: no information regarding it is divulged to the company, so that the policy-holder cannot be adversely affected with regard to possible future proposals.

Value of Periodic Examination.

Recently there has been considerable discussion in this country as to the value of periodical examinations, and about a year ago a special meeting was convened by the Federation of Medical and Allied Services with the object of passing a resolution in favour of a similar service by British life companies. At that meeting the lay speakers seemed to assume that the detection of early disease by such an examination presented no real difficulty. They failed to realise that, in many cases, the examination could be only the preliminary to accurate diagnosis. Suppose, for example, that it revealed a trace of glycosuria. What are the alternatives? If the examiner is referred to his family doctor, he may or may not go to him. If he does, in how many cases will the practitioner really investigate the sugar metabolism on the modern lines necessary to arrive at a correct estimation of the significance of the glycosuria? If, on the other hand, the examinee is referred to a specialist, is he willing to incur the considerable expense entailed thereby? And, if the result is favourable, will he be pleased with the company for providing him with a "free" overhaul that involves him in a considerable outlay which he feels to have been unnecessary? Exactly similar difficulties would arise in the case of many other conditions—slightly increased blood pressure, slight pulmonary catarrh, vague dyspeptic symptoms, albuminuria, and so on. It seems to me that either the company should be prepared to carry out the whole investigation of any abnormality detected in the course of the examination, or it should leave the policy-holder entirely to his own resources. The tendency of the ordinary "routine examination" will be to find out too much or too little—to interfere unnecessarily with the comfort and peace of mind of the examinee, or to lull him into an unwarranted complacency.

¹ For most of the facts in this section I am indebted to an address delivered in October, 1921, at the Annual Meeting of the Association of Life Insurance Medical Directors by the President, Augustus S. Knight, M.D.

Results of the Service.

As regards the actual results of the service, Dr. Knight's address gives some interesting figures. During the period under review, 1914-21, only 2.49 per cent. of the number eligible actually underwent medical examination. This does not look as though policy-holders were really anxious to avail themselves of the privilege. A careful statistical study was undertaken of the mortality experience up to November, 1920, of about 6000 males who presented themselves for this examination in 1914 and 1915. For this purpose the examination records were put at the disposal of the company by the Examination Institute. From these data the whole group was divided into four sub-groups according to the physical conditions revealed by examination: (1) "Preferred risks" (exceptionally good lives) (9181 policy-years); (2) "ordinary risks" (7111 policy-years); (3) "cases with albuminuria" (9850 policy-years); (4) "miscellaneous group" (with various impairments) (7485 policy-years).

The mortality experience was as follows. [Ratio of Actual Deaths to Expected by American Men (Ultimate Table).] (1) 47 per cent.; (2) 72 per cent.; (3) 46 per cent.; (4) 117 per cent. For the whole group it was 72 per cent.

Number of cases which presented themselves for a second examination: Subgroup (1) 41 per cent.; (2) 37 per cent.; (3) 33 per cent.; (4) ? (not given in Dr. Knight's paper).

These figures are of great interest, as they throw light on the answer to the question—To what type of policy-holder does the periodical examination appeal? Of the very few (2.5 per cent.) who availed themselves of the opportunity of a first "periodical examination" only about 30-40 per cent. took the trouble to appear a second time. The highest percentage was in the group who were physically fittest—i.e., who were least in need of it. The lowest percentage was among those who were told that they had a definite disability—albuminuria. In other words, it certainly seems that the people who are most anxious to avail themselves are those who are least in need of it; that it is the man who feels well who likes to come and be assured that he is well. To him the periodical medical examination is a species of self-indulgence; his vanity is tickled by his being pronounced "fit."

I have no time to quote Dr. Knight's exhaustive analysis of the mortality in these cases; he comes, by a different route, to the conclusion just mentioned as to the strong element of self-selection in those availing themselves of periodical examination—namely, that the privilege is made use of in inverse ratio to its utility. But to me the most striking sentence in his paper is as follows: "It would therefore be safe to say that the benefits of the life extension examinations are pretty well limited to the years immediately following the examinations, and run out at the end of about five years." I do not quite understand from the context what is the exact meaning of this sentence, whether the protection lasts five years from the date of the first periodical examination or the last. Judging, however, by the figures quoted above, it does not seem that there is any great distinction between these two alternatives—the first examination seems so often to be the last!

In spite of these limitations, the Metropolitan calculate that they are making a handsome profit on balance on the expenditure incurred in this scheme. So far as I know, in this country only two life offices have so far initiated any scheme of periodical examination for their policy-holders, and the experiment is too recent to allow any judgment of its value.

To recapitulate the pros and cons of such a scheme, it seems to me that, in theory, it is an excellent

principle, which should result in mutual benefit to the office and to the individual policy-holder. In practice, however, its success would seem to be impaired by the following difficulties: (1) The incompleteness of the arrangements for a really effective diagnostic service, including the difficulty of efficient medical personnel; and (2) lack of interest among the policy-holders, of whom the great majority fail to make use of the facilities provided; among those that do, there appears to be a "selection" in favour of those whom it benefits least; and of those who do avail themselves of a first examination, comparatively few persevere by undergoing subsequent re-examination.

THE PREDISPOSING CAUSES OF LEPROSY.

By E. MUIR, M.D., F.R.C.S. EDIN.,

RESEARCH WORKER IN LEPROSY AT THE SCHOOL OF TROPICAL MEDICINE AND HYGIENE, CALCUTTA.

MUCH of the confusion which exists with regard to leprosy is due to the want of recognition of the important rôle played by predisposing causes. There is probably no disease in which predisposing causes play a more important part than in leprosy. Many facts might be quoted to prove that healthy human beings, like the lower animals, are insusceptible to leprosy, that although the bacilli may be present in the body some predisposing cause or other is necessary before they can begin to increase in number and produce signs. Moreover, the course of the disease is profoundly affected by the nature, degree, and number of the predisposing causes. I have therefore considered it useful to study in this paper some of the commoner predisposing causes and their effects on leprosy.

Predisposing causes may be conveniently divided into temporary or self-terminating and permanent.

Temporary or Self-Curing Predisposing Causes.

These from their nature last but a short time, and while they last are accompanied either by the first signs of leprosy or by an increase in previously existing signs. They include all the acute febrile diseases such as enteric, influenza, small-pox, and other exanthemata. To take a typical case.

A female patient had a small, anæsthetic, leprosy patch on her arm, which was her only sign of the disease. She developed enteric fever, and during convalescence an erythematous rash spread in patches all over the body within a few weeks. The patches were raised and contained lepra bacilli. As the patient recovered her strength the patches began to fade in colour and became flattened out to the level of the surrounding skin. The enteric had lowered the resistance of the patient and made her tissues a suitable soil for the growth of *B. lepræ*. As the resistance returned the soil became unsuitable once more and the bacilli began to disappear.

Another case was that of a patient who had had a severe attack of influenza. The signs, formerly consisting of a small anæsthetic patch on the arm, rapidly increased to deep nodulation of the back, arm, face, and ear, which again rapidly recovered as the patient regained his strength. Treatment was given, but the recovery was much more rapid than could have been expected as the result of treatment alone.

In both these cases the rapid increase of leprosy signs took place in the afebrile period immediately following the febrile period of the predisposing disease.

Pregnancy is another common cause of the onset and increase of leprosy. The extra strain thrown on the system, especially in women who cease to take open-air exercise as pregnancy advances, is sufficient to cause the required conditions. Puberty, especially in poorly-nourished, rapidly-growing children, is often accompanied by the first signs of leprosy, or, if they have been present before, by their rapid increase. Besides the above, similar results may be caused by any circumstances which temporarily lower the

² This low mortality for albuminuria cases in the first five years of insurance is extremely interesting. (Cf. the American Medico-Actuarial Investigation figures for cases of albuminuria—mortality 78 per cent. for first five years, and 200 per cent. for next five years.)

resistance of the body such as change of diet, injuries, unfavourable climate or surroundings, vaccination, &c.

Permanent Predisposing Causes.

These differ from the above in that they do not tend to cease spontaneously. Syphilis, chronic bowel disorders, fevers of protozoal origin, such as malaria and kala-azar, are typical of such permanent causes; but any cause which weakens resistance and tends to remain for a prolonged period, whether it be biological, climatic, or social, may be included under this heading. We shall consider the more important, permanent predisposing causes seriatim.

(a) *Syphilis*.—A connexion between syphilis and leprosy has long been recognised. Impey¹ classes "syphilitic leprosy" as one of the four forms of the disease. There is a popular idea in India that leprosy and syphilis are different forms of the same disease. In a paper dealing with the Effect of Antisyphilitic Treatment in Leprosy,² it has been shown that anti-syphilitic treatment has a marked power to render a positive Wassermann reaction in leprosy negative, especially in early nerve cases; and we came to the conclusion that syphilis is an important complicating factor in both skin and nerve leprosy. The history of the first onset of leprosy following an attack of syphilis is very common; and when those who have been suffering from leprosy in a mild form contract syphilis, the former disease generally takes on a much more virulent form. There is no evidence that there is any ætiological connexion between the two diseases, but syphilis acts as a predisposing cause, and renders the human tissues a suitable soil for the growth of the lepra bacillus. It would therefore be expected that, other things being equal, the proportion of lepers would be higher among the syphilitic than among the non-syphilitic population, and as a corollary that the proportion of positive W.R.'s would be higher among lepers than among non-lepers. As a matter of fact this is found to be the case, although the high Wassermann rate cannot be entirely attributed to syphilis.³ An excellent prognosis can generally be given in an early case of leprosy when the W.R. is positive, as the predisposing cause, syphilis, is easily removed, and, as a rule, the leprosy infection dies out rapidly after the removal of such a strong predisposing cause. In more advanced cases of leprosy, on the other hand, the prognosis in a positive W.R., though good, is not as good as in early cases, as there is not the same certainty that the W.R. indicates syphilis, and even when syphilis is the cause and has been removed there is still the leprosy infiltration to deal with, which may take some years.

(b) *Chronic Bowel Disorders*.—Next to syphilis chronic bowel disorders form, perhaps, the most important permanent factor. Among these the most important in India are the dysenteries, amœbic and bacillary, and the chronic conditions which they frequently leave behind. Chronic constipation, with the absorption of toxins from the bowel, forms a most favourable condition for the growth of leprosy. This, unfortunately, is a condition which it is often very difficult to remedy, and in such cases the prognosis with regard to leprosy is rendered less favourable.

(c) *Malaria* is another common predisposing cause in India, especially benign tertian, which is sometimes very difficult to cure with quinine.

(d) In Bengal we have frequently found the first signs of leprosy appearing during an attack of kala-azar, after the fever has yielded to treatment.

(e) *Hookworm disease* strongly predisposes to leprosy. In five leper asylums, the inmates of which were examined for hookworm, an average of 90 per cent. were found infected. In one asylum only three were found uninfected. Remarkable improvement is often noticed in leper asylums after mass treatment for hookworm has been carried out.

(f) *Unsuitable diet* is another frequent predisposing cause. Hutchinson emphasised—and possibly over-

emphasised—this fact in his theory that leprosy is due to fish eating, or rather, as he defined it later, the eating of badly preserved or decomposed fish. There is no doubt that this is a predisposing cause. Hutchinson's mistake was in making it the only predisposing cause and in ignoring the importance of the lepra bacilli and their transmission by contact with infectious lepers. Stale, badly preserved food, whether it be fish or meat, rice or grain, fruit or vegetables, predisposes to leprosy. Overcooked, twice cooked, and badly cooked food is also injurious.

(g) *Climate* is another consideration of great importance. Sir Leonard Rogers has proved,⁴ by carefully collected evidence, that the incidence of leprosy closely corresponds with the humidity of the climate. Neither heat nor cold alone predisposes to leprosy, but both heat and cold accompanied by high humidity correspond with a high incidence. In this respect leprosy closely resembles tuberculosis.

(h) The importance of the *mental condition* of the patient must not be lost sight of in leprosy. In a disease which is so much dreaded and which brings with it social ostracism and loss of employment, mental depression, followed as it generally is by physical depression, is very common and plays not a small part in causing the progress of the disease.

(i) *Lack of exercise* is another important cause. *B. lepræ* lives and multiplies in the intercellular lymph spaces, and lymph stagnation is favourable for its growth. Vigorous exercise is always an essential for the treatment of leprosy, while on the contrary lazy and sluggish habits predispose to the disease. This is not uncommonly the reason why, when people of active habits retire from work and adopt a sedentary life the signs of leprosy begin to show themselves. It is also to a large extent the reason why leprosy is common among the rich. Employers not infrequently dismiss their employees on hearing that they are suffering from leprosy, whether or not the disease has reached a stage at which it is transmissible. This loss of employment, along with the accompanying mental depression, often leads to sluggish habits, and thus as an indirect result of the disease itself a powerful predisposing cause is brought into play which leads to its rapid increase.

(j) *Youth* has often been indicated as predisposing to leprosy. The fact, brought out by Rogers,⁵ that about 50 per cent. of lepers are infected before the age of 20 certainly points to youth as the most common period for acquiring leprosy.

(k) *Puberty and pregnancy* are certainly predisposing factors, as they are in many other ways critical periods in the life-history. Moreover, on the principle that the closer the contact the greater the chance of infection, the early years of life expose to infection if the parents, guardians, friends, or relations are infectious lepers, as children are handled and cared for and kept in constant close contact with their elders, and their skin is thin and tender and much more frequently abraded than that of adults. Apart, however, from the greater chances of infection and the crises of puberty and pregnancy which are liable to light up latent infection, youth does not directly predispose to leprosy to a greater extent than other periods of life.

Another critical period is the *climacteric* in women which is not infrequently accompanied by the onset of the disease.

Though leprosy is generally confined to the first three or four decades, it is not altogether uncommon to find its onset in more advanced periods of life. To give one typical example.

A patient acquired syphilis at the age of 20. The disease gave him only slight inconvenience and he was not treated for it effectively. At the age of 68 he began to show signs of leprosy, which increased rapidly till the B₂ form of the disease was reached (see diagram). When he was 75 years of age he came for treatment, and his W.R. was found to be strongly positive. A course of antisyphilitic treatment had a marked effect, the lesions disappearing to a very large extent.

Predisposing Causes in Relation to Prognosis and Treatment.

We may expect to find one or more predisposing causes in every case of leprosy, though, while in some cases the cause is apparent, in others it is obscure. It may be taken as an axiom that the more distinct and removable the predisposing cause the better the prognosis with regard to leprosy. To try to treat a case of leprosy by special treatment without first removing the predisposing cause is like trying to drive a motor-car up hill with the hand-brake full on. Therefore, from the point of view both of prognosis and treatment, the recognition of the predisposing cause is of first importance.

Effect of Febrile Illnesses on Leprosy.—A curious phenomenon, however, is noticeable with regard to many of the predisposing causes mentioned above, especially those which produce a febrile condition. In the more advanced stages of leprosy such fevers instead of causing an increase of the disease tend to cause its resolution and disappearance. Within the last 12 months I have had under my treatment ten patients who developed kala-azar while in an advanced stage of skin leprosy. All of them without exception improved rapidly as far as leprosy was concerned, nodules and skin infiltration rapidly disappearing. Indeed, they made far better progress under the effect of kala-azar than under any form of special treatment. One very advanced case of leprosy, with abundant *B. lepræ* infiltrating the skin of face, trunk, and limbs, developed acute exfoliating dermatitis and died of pericarditis after two months' illness. Post mortem we were unable to find more than a few granular bacilli, the acute febrile condition having caused almost complete destruction of the acid-fast bacilli. I have noticed similar but less marked improvement after dengue fever, cholera, malaria, dysentery, and even after pregnancy. Trophic abscesses in the limbs when accompanied by inflammation and fever will cause rapid disappearance of both skin and nerve lesions.

Leprosy a Self-curing Disease.

I have described leprosy in a former paper⁶ as a self-curing disease and give here a diagrammatic representation of this process in different types and

Leprosy curves. A = nerve (anæsthetic) leprosy. A₁ = primary nerve leprosy. A₂ = secondary nerve leprosy. B = skin (nodular) leprosy. B₁ = first stage of same; free bacilli found in the skin. B₂ = second stage; more bacilli found in the skin. B₃ = third stage; very marked, generalised infiltration, abundant bacilli. —> = reaction-producing granulomatous causes.

stages of leprosy. Typical examples of the course followed by leprosy are illustrated by various curves, the perpendicular representing the number of bacilli in the body, and the horizontal the length of time. All cases pass through the A₁ stage, though some cases are difficult to recognise before they reach the B₁ stage.

In cases which are mild in type the disease may remain at the A₁ level, or it may pass on into B₁, B₂, or B₃. At any height, however, the curve may reach its uppermost limit or climax if the resistance of the body is raised sufficiently, as by the removal of the predisposing cause, either naturally, or as the

result of treatment, or, as we find it chiefly in the higher curves, by the induction of immunity following on the breaking down of leprosy tissue. In other words, the top of the curve corresponds to the point at which the general or special resistance of the body becomes sufficient to withstand the advance of leprosy. The febrile and other predisposing causes mentioned in the last paragraph as causing improvement in the advanced stages of leprosy may be termed potential reaction-producing causes. These are represented in the diagram as arrows.

We may consider such causes as forces applied in the directions of the arrows to bodies ascending or descending the curves. In the former, the body would tend to ascend more rapidly (and the steeper the curve the more so); in the latter the body would tend to descend more rapidly. In other words, when reaction-producing causes come into play during the rise of the curve they tend to make the disease increase; when they come into play during the fall of the curve they hasten recovery.

Part of the effect of various drugs used in leprosy, though not always the most important part, is due to this reaction-producing power which they possess in common with the febrile and other causes mentioned above. It will therefore be clear that in patients who have not reached the climax of the disease, and whose curve may still be represented as on the upward gradient, special treatment may have to be applied with care until the predisposing cause has been eliminated, and the general health and resistance of the patient improved. On the other hand, the injection of preparations of hydnocarpus and chaulmoogra oils has often the effect of arresting the disease and bringing about its gradual elimination, even in spite of the presence of minor predisposing causes.

The objection may be raised that if leprosy is a self-curing disease then why remedy it, why not let the curve take its natural course seeing it will reach the base line again in the end? The object of the removal of predisposing causes and of special treatment is to flatten the curve, to bring about the crisis as soon as possible, and to hasten the down-grade of the curve. Most of the deformities of lepers are due to lingering on the down-grade as the type passes from B₃ down to A₂. To avoid this, vigorous treatment must be applied when once the signs of the disease have begun to diminish and, above all, sluggishness must be avoided, as of all the predisposing causes it is perhaps the most common and most harmful. Moreover, vigorous exercise enables vigorous treatment with hydnocarpus ester injections to be borne without excessive reactions, and in this way improvement can be hastened.

Summary.

1. It is maintained that in almost all cases the onset of leprosy is due to some predisposing cause in conjunction with infection with *B. lepræ*.
2. Some of these will remove themselves; of the rest the majority can be removed by treatment.
3. Certain of these causes which predispose to the onset of the disease and to its increase in the first stages tend to bring about resolution of the lesions and general improvement in later stages.
4. It is essential to remove predisposing causes as far as possible before carrying out vigorous special treatment, as otherwise the latter may cause an increase rather than a diminution of the disease.
5. Most deformities in leprosy are due to the lack of vigorous treatment in the later stages of the disease.

BREAST DISEASE AND THE *DEMODOX FOLLICULORUM*.

BY HELEN CHAMBERS, C.B.E., M.D. LOND.,*

AND

A. MILLICENT SOMERSET.

(From the Cancer Research Laboratories of the Middlesex Hospital.)

IN 1909 Borrel,¹ in collaboration with Gastinel and Gorescu, found an acarus living in the sebaceous glands at the orifice of the nipple in six cases of breast cancer. He put forward the hypothesis that the acarus transmitted a virus infection, and that the cancer was caused by this virus. The importance of this hypothesis lies in the suggestion that breast cancer is caused by some agent conveyed to the patient from outside through the nipple, for, clearly, if there is any truth in this theory, it should be possible to take effective preventive measures. Borrel's work has attracted very little attention in this country, and we have not been able to find any confirmation of his results in the literature. In view of our complete ignorance of the cause of breast disease, it seemed desirable to investigate and determine whether any data could be found in support of this theory.

During the last year, owing to the kindness of the medical staff of the Middlesex Hospital, and especially of Mr. Sampson Handley, we have had the opportunity of examining 63 breast specimens removed by operation, and have been able to confirm Borrel's finding that an acarus lives at the orifice of the nipple in a large percentage (nearly 60) of patients with breast cancer. The parasite has been found in breasts removed for mastitis and for papillomatous growths, and also in a few post-mortem cases when the patients have not, during life, complained of any breast trouble. It occurs apparently irrespective of the social class or personal habits of the patient, for it has been found in nine private cases out of a total of ten examined.

The *Demodex folliculorum* has been known for many years; it was found in man by Berger and Heale in 1841, and by Simon in 1842. It was first described in the dog by Tulk in 1844. Wagner in 1876 states that it is present in most men in the sebaceous glands around the external ear and face. Usually looked upon as harmless, it has been credited with causing impetigo (Lawrence), and inflammation of the Meibomian glands (Hausche and Jores). A similar type of acarus occurs very generally in animals and has been found in cats, dogs, rabbits, rats, goats, swine, and cattle. The demodex mange of dogs and cattle is said to be incurable, owing to the depth into the skin that the parasite penetrates.

Borrel, in France, examined the normal skin of 20 human cases, and found the demodex in 50 per cent. He thought that it was specially numerous in patients with cancer, and described 12 cases of rodent ulcer in which the acarus occurred in very large numbers immediately around the site where the malignant growth started. The parasite was found in six cases of breast cancer out of a total of seven examined, sometimes more than 100 were present in one nipple. Borrel has been a strong adherent of the theory of the parasitic origin of cancer for years, and he has collected many cases of malignant disease, both in man and animals, in which the growth apparently started around the site where some form of parasite had lodged. In the case of the demodex, although he was very careful not to draw conclusions beyond those which the data warranted, he strongly advocated that means should be adopted to rid

mankind of this pest. He looked upon the demodex as transmitted by close contact and family relationships, and suggested that its presence would explain the existence of so-called cancer houses and the so-called hereditary nature of cancer.

Method of Examination.

The method adopted by Borrel consisted in cutting serial sections of the nipple parallel to the surface of the skin. At first we followed this laborious technique; but it has since been modified and is now as follows:—

The breast is brought from the theatre soon after removal. The nipple is cut in half across the centre with scissors and one half put into fixative for microscopic examination. From the other half pieces of the nipple skin are cut about 1 mm. in thickness; the central pieces are taken first, as they contain, as a rule, most of the sebaceous glands. The cut surfaces of the strip are scraped in water on a slide, and the scrapings examined with 2/3rd and 1/6th objectives. The parasites are easily detected and their very distinctive structure leaves no doubt of their identity. In some cases as many as 12 or more are found on the first slide, in other cases only one or two are found in the whole nipple. The acarus has not yet been found by taking scrapings from the surface of the nipple of the living patient.

The *Demodex Folliculorum*.

The acarus is shown in the figure. It is about 0.3 mm. long, the male being smaller than the female.

The length is variable, and much smaller forms are met with when young. It lives head downwards in the sebaceous glands, and is commonly found in pairs, male and female, living together in close apposition. Sometimes as many as 20 parasites are found in one sebaceous follicle. The eggs are oval and are laid in the glands; they hatch out larvæ with only three pairs of legs instead of the four pairs which the adult form possesses. In most of the specimens the acari have not been numerous, and the eggs have been difficult to find.

The parasite protects itself from adverse conditions by burrowing deeply into the glands, and it has frequently been found alive in specimens removed by operation after the skin has been carefully disinfected for surgical reasons with alcoholic iodine or alcoholic picric acid. The acarus shows no tendency to leave the specimen after removal from the body, and it has been found alive eight days later in breasts which have been kept at room temperature and in which autolytic changes have been well advanced.

* Full-time investigator for the Medical Research Council.

¹ Borrel, A., Gastinel, P., and Gorescu, C.: *Acariens et Cancres*, Annales de l'Institut Pasteur, 1909, xxiii., 97.

Septic contamination quickly kills it. The acarus has been often seen in active movement, but attempts to cultivate it outside the body have so far not met with success.

Microscopic Changes.

Borrel stated that the sebaceous glands harbouring this parasite showed signs of chronic inflammation, and that he found it burrowing into the cellular tissues. We have not been able to confirm the latter part of this statement. Marked signs of chronic inflammation around the follicles have often been seen; in other cases, however, they have been entirely absent. Inflammatory changes associated with plugs of debris and bacteria in the orifices of the glands have occasionally been the first changes noted when the acarus has only been found after prolonged search. In a few cases inflamed gland acini have been found in close contact with the deepest parts of the sebaceous glands, almost looking as if a direct transmission of infection had occurred. This appearance has been traced sometimes in the breast quite apart from the nipple. Borrel thought the sebaceous glands increased in numbers owing to the irritating action of the parasites. In the cases recorded here the glands have sometimes been very numerous when no acari could be found at all. On the other hand, in cases where the acari have been very numerous, there have been comparatively few glands.

The Cases Examined.

Sixty-three breast cases have been examined; the details are given in the following table:—

Disease.	No. of cases in which the acarus was—		Total.
	Found.	Not found.	
Carcinoma	26	20	46
Papilloma	2	1	3
Chronic mastitis ..	8	5	13
Fibro-adenoma ..	1	0	1
—	37	26	63

There has been no opportunity of finding the incidence of infection among the general population. Seven normal breasts only have been obtained, and in these the acarus was present in two. Both were post-mortem cases from patients who had died from carcinoma, but in some other region of the body than the breast. The list of cases given in the table includes four males; the acarus was found in three of these, one had carcinoma of the breast, the other two had chronic mastitis. There was no reason to suppose in any of these cases that the acarus was limited to the region of the breast. It has been found on the chest wall, in the axilla, and in a case of epithelioma of the vulva on the mons veneris. The parasites are often so few in number, and there is so little sign of chronic irritation around the site where they are lodged, that it seems to the writers doubtful whether they have any direct bearing on the disease. On the other hand, the site where they live at the orifice of the nipple and their burrowing habits give them every facility to transmit a living virus if this is present.

Experimental Inoculations.

To obtain direct evidence that breast disease is caused by the agency of the *Demodex folliculorum* it would be necessary to produce the disease in animals. With this object emulsions containing the acarus have been inoculated subcutaneously into the breast region of a number of mice and rats.

Emulsions containing the parasite in fairly large numbers were obtained by the method already described, using sterile conditions. Each animal received four to six acari. In all, 47 animals were treated, 36 mice and 11 rats. The results were

entirely negative. At the end of three months 22 mice and 11 rats were alive, and at the end of four and a half months 11 mice and 11 rats were alive and well. This method of subcutaneous inoculation does not produce a chronic condition at all comparable with the chronic irritation so often found in the breast ducts in the human subject. To inoculate the breast ducts requires larger animals than those which have been available.

Conclusions.

1. Breast disease in England is often associated with the presence of an acarus which lives at the orifice of the nipple. This acarus apparently is prevalent irrespective of the social class or personal habits of the patient. It lives deeply in the sebaceous glands and is not killed by treatment of the skin with strong antiseptics; it can remain alive for over a week buried in the skin. Any form of preventive measures must, therefore, be long continued and must aim at destroying the acarus when it comes to the surface.

2. It has been suggested by Borrel that this parasite can convey to the breast ducts a living virus which can set up malignant disease. At present there is no evidence to support or to disprove this theory.

ETHYLENE ANÆSTHESIA,

WITH OBSERVATIONS UPON ONE HUNDRED AND TWENTY ADMINISTRATIONS.

BY C. LANGTON HEWER, M.B., B.S. LOND.,

ANÆSTHETIST TO ST. BARTHOLOMEW'S AND THE ALBERT DOCK HOSPITALS; SENIOR ANÆSTHETIST TO THE QUEEN'S HOSPITAL FOR CHILDREN.

ETHYLENE or olefiant gas is an unsaturated hydrocarbon having the formula C_2H_4 . The narcotic action of the gas is said to have been discovered by Simpson and investigated by Nunnally, of Leeds, but it is doubtful whether these early workers ever anæsthetised patients with it. The recent observation that ethylene dissolved in pure ether alters its anæsthetic properties revived interest in the gas, and its actions have been thoroughly worked out by Luckhardt, Carter and Easson Brown in America.

Preparation.

Until recently it has been impossible to obtain pure commercial ethylene in Great Britain, and most of the gas used in the following cases has been kindly prepared by Dr. W. H. Hurtley, lecturer in chemistry to St. Bartholomew's Hospital. The method of preparation is known as Newth's process, and is briefly as follows: Syrupy phosphoric acid is heated in a round-bottomed flask to drive off water. A thermometer is placed with its bulb in the liquid, and boiling occurs at about $160^{\circ}C$. The heating is continued until the temperature rises to $200^{\circ}C$. At this stage the flask is fitted with a cork carrying (1) the thermometer, (2) a tap-funnel whose stem reaches below the surface of the liquid, and (3) a delivery tube connected to a wash-bottle standing in ice. Ethyl alcohol is then allowed to drop slowly on to the acid from the tap-funnel, the temperature of the mixture is kept at about $220^{\circ}C$. and the ethylene collected over water. This method can be used commercially, and would be comparatively inexpensive, provided that duty-free spirit could be employed. The gas so prepared was compressed at a relatively low pressure (100 lb. per square inch) into ordinary nitrous oxide cylinders by means of an adapted motor-tyre pump. The remainder of the gas was imported from America to ascertain whether there was any appreciable difference in quality. It was found that the smell of the imported ethylene was pungent and resembled that of acetylene, while the other gas had a rather pleasant ethereal odour. At the same time there appeared to be no appreciable difference in the effects of the two gases on patients,

and the American ethylene when examined was shown to have a purity exceeding 99 per cent.

Properties.

The odour of ethylene has already been mentioned and will be referred to again later. The main point of interest to the anæsthetist is the inflammability and explosibility of the gas. Pure ethylene burns with a semi-luminous flame in the same way as hydrogen. A mixture of between 4 per cent. and 15 per cent. ethylene in air explodes with moderate violence in the presence of an electric spark. Mixtures of oxygen and ethylene explode with extreme violence if the oxygen percentage exceeds 40. It should also be observed that in this respect nitrous oxide acts in a similar manner to oxygen, a point to be borne in mind if anæsthesia is induced with nitrous oxide and continued with ethylene. From these considerations it will be seen that the only likelihood of danger from explosion in practical work lies in (1) the application of any type of cautery to the region of the face or mouth if the patient is anæsthetised with ethylene or mixtures of this gas with nitrous oxide or oxygen; (2) in cases where a double-airway endotracheal ethylene-oxygen anæsthesia is being given and the blast of the return airway is directed towards a naked flame, such as that of a steriliser; (3) in passing a tracheal catheter by means of a direct-vision laryngoscope with distal illumination. An imperfect contact or short circuit of the lamp might cause a minute spark, and for this reason the writer has now ceased inducing anæsthesia with ethylene-oxygen if a tracheal catheter is to be passed.

The question of spontaneous explosion must now be considered. Ethylene being an endothermic gas, it was thought possible that under high pressure explosion might occur in a similar way to acetylene. This fear, however, appears to be groundless, as in America thousands of cylinders of ethylene have been compressed to about 60 atmospheres and explosions are unknown. At this pressure, however, ethylene behaves in a curious way. The critical temperature of the gas is given by various authorities as between 10° C. and 13° C. In spite of this, ethylene compressed to 870 lb. per square inch at 18° C. does not behave as a gas, but follows no definite laws of pressure and volume, being apparently in some border-line condition between the gaseous and liquid states.

From these observations it will be seen that if ordinary care is used ethylene is safe, but it should be remembered that were an explosion to occur the consequences would be very different from those following the alarming, but comparatively harmless "ether flare," but will probably involve the death of the patient and serious injuries to the anæsthetist and other occupants of the theatre. One such explosion, involving the death of three persons, has recently occurred in America.

[Physiological Action.

Ethylene has an extremely powerful action on certain plants. For example, it was noted 15 years ago by Crocker and Knight that ethylene, in a concentration of 1 to 2,000,000 parts of air, caused open carnations to close. Upon animals and man a concentration of over 75 per cent. acts as an analgesic and anæsthetic. Spectroscopic examination of the blood drawn from patients under ethylene anæsthesia does not reveal any absorption bands, showing that the gas does not combine with the hæmoglobin, but is probably in a state of physical solution in the plasma. On discontinuing the administration the gas is very quickly eliminated, although traces can be detected in the breath for several hours.

The systolic and diastolic blood pressures and the pulse-rate appear to be practically unaffected by ethylene, provided that enough oxygen is given to avoid cyanosis. If this is allowed to develop, the pressures naturally rise. The depth and rate of respiration are also unaltered, provided that means are

taken to avoid accumulation of carbon dioxide. Muscular relaxation is a variable factor. All minor operations, except possibly the reduction of dislocations, can be performed under ethylene-oxygen alone, but most abdominal sections require the addition of ether or chloroform. There is no chemical action between these compounds, and the necessary amount of vapour can be added in the anæsthetic bottle of a sight-feed gas and oxygen machine.

To sum up, the general picture of a patient under ethylene-oxygen anæsthesia resembles one of natural sleep with a pink colour, normal pulse-rate and blood pressure, and with shallow regular breathing, the corneal reflex being present.

Administration.

Ethylene has been administered in a variety of ways as follows:—

1. *Ethylene and Air*, given with the usual simple gas apparatus. This method is quite satisfactory for short minor operations, such as dental extractions, the opening of abscesses, and the like. In dental cases the nasal method can be employed for the prolongation of anæsthesia in exactly the same way as with nitrous oxide.

2. *Ethylene-oxygen* with partial re-breathing. The writer has employed an ordinary Boyle's sight-feed gas and oxygen machine for this purpose and finds it quite satisfactory. It is wise, however, to check the enthusiasm of the nurse who lights the spirit-lamp on the older patterns of the machine to warm the reducing valves. The great feature of this method is that the majority of patients can be kept anæsthetised indefinitely on a mixture of 80–85 per cent. ethylene and 15–20 per cent. oxygen with no added ether. The result is a patient lying quite still with a pink colour. Most anæsthetists will agree that this is impossible with a pure gas-oxygen. Relaxation varies, but for abdominal cases some added ether is nearly always necessary.

3. *Ethylene-oxygen with Carbon Dioxide Absorption* and complete re-breathing. Since ethylene is exhaled

from the lungs unchanged, it follows that the same gas can be used again. The diagram illustrates the principle of the method. The two-gallon gas-bag contains the ethylene-oxygen mixture, and "to-and-fro" breathing takes place through a metal chamber containing granulated soda-lime to absorb the carbon dioxide. Sufficient oxygen is added to keep the colour pink. In practice a certain amount of leakage occurs and more ethylene must be added at intervals, but even so the method is extremely economical, as only about five gallons of gas are used in half an hour. The soda-lime must be changed when caked, but this does not occur till after four hours' use with a normal-sized filter. The most convenient apparatus to use is a Boyle's machine with the filter interposed between the bag and the face-piece, the stopcock being in the "no valves" position.

4. *Endo-tracheal Ethylene-oxygen*.—The writer has induced anæsthesia on several patients with ethylene-oxygen and then passed a tracheal catheter, continuing with endo-tracheal ethylene-oxygen. As previously

mentioned, although sufficient relaxation can be obtained to pass the catheter easily, the chance of explosion seems to render the method somewhat risky. Anæsthesia can be maintained with pure ethylene-oxygen, provided that the oxygen percentage is not allowed to rise too high, but for abdominal work or in other cases where great relaxation is required, some ether must be added.

Results.

The results obtained in the first 120 administrations of ethylene will now be summarised. The operations included abdominal exploration, amputation of the breast, excision of cysts, glands, ganglia and polypi, incision and drainage of abscesses, suture of tendons, circumcision, tonsillectomy, and dental extractions. The total time of anæsthesia varied between two and 58 minutes, while the age of the patients was from 2 to 62 years.

The average time for the induction of anæsthesia was 1 minute 50 seconds. No case gave rise to any anxiety during operation. Anæsthesia was completely satisfactory in 110 cases with ethylene or ethylene-oxygen only. In five of the remaining patients a little ether had to be added to secure the necessary relaxation. The rest of the unsatisfactory cases were all dental extractions which exceeded the estimated time, a nasal apparatus not being available. If this could have been used there is no reason to suppose that the anæsthesia could not have been extended to enable all the extractions to be completed. The "single-dose" method usually gives about 1½ minutes anæsthesia, which is longer than with a "straight gas" and rather shorter than with closed ethyl chloride.

After-Effects.

The noticeable lack of after-effects constitutes the chief advantage of ethylene anæsthesia. Out of 120 cases, only ten vomited at all and two of these had some additional ether. Most patients exhibit some aphasia for a few minutes after coming round, but if the time of anæsthesia has not exceeded ten minutes, they can usually walk without assistance three minutes after the face-piece has been removed. All the adult patients were questioned as to the smell, but only two complained at all strongly, the vast majority thinking that they had had nitrous oxide. From personal observation, the odour is distinctly perceptible for the first few breaths, but then becomes unnoticeable, as unconsciousness rapidly supervenes. The odour in the theatre is unusual, but is never strong enough to become a nuisance.

Patients are remarkably fit after ethylene anæsthesia. A good comparison with ethyl chloride was afforded by children having multiple dental extractions. Seventy per cent. of the patients who had had ethyl chloride vomited, and they had to be kept under observation for an average of 35 minutes. None of the children anæsthetised with ethylene vomited (59 cases), and they could be sent home after an average of ten minutes.

Conclusion.

These results agree substantially with the reports of large numbers of cases anæsthetised with ethylene in America, and appear to show that this gas has certain advantages over the other anæsthetics at present in use, especially for minor operations taking a moderate time and which require more than nitrous oxide.

The writer understands that limited quantities of ethylene are now available from Messrs. Coxeter, Pancras-road, N.W. 1. He wishes to express his thanks to Dr. W. H. Hurtley for the preparation of the gas and to Mr. Geoffrey Carte, Mr. T. P. Dunhill, and Mr. S. A. Withers for permission to anæsthetise their cases with ethylene. The majority of the cases cited above were anæsthetised at St. Bartholomew's Hospital and the Queen's Hospital for Children.

Clinical and Laboratory Notes.

TWO CASES OF ACUTE POLIO-ENCEPHALITIS.

By E. A. B. POOLE, M.D. DURH., M.H.,
D.P.H. LIVERP.,

MEDICAL OFFICER OF HEALTH, TAUNTON RURAL DISTRICT;
MEDICAL OFFICER, TAUNTON JOINT ISOLATION HOSPITAL.

RECENTLY, the two following cases of unusual infectious disease were admitted to the Taunton Joint Isolation Hospital, which seem worthy of record:—

CASE 1.—Male aged 17. Sent in from the local general hospital as a case of encephalitis lethargica.

Condition on Admission.—He had swelling about the throat, difficulty in speaking and swallowing, tonsils enlarged, fauces reddened, temperature normal; he had symptoms of bulbar paralysis and weakness of muscles of right leg. His face was dusky in appearance, and he was in great distress; there was no ankle-clonus, no Babinski sign, and the reflexes were very much diminished. Heart and lungs normal, no implication of the third nerve, and no history of double vision. He had moderate headache, marked retraction of the head, and Kernig's sign plus. He died ten hours after admission from failure of respiration, with a clear mind and no lethargy or mental symptoms.

The cerebro-spinal fluid was clear and not under increased pressure. The laboratory report was: Some alteration in the cellular elements; polynuclears in increased proportion. No organisms present; slight globulin reaction. Probably a case of aseptic meningitis.

I was informed by the house surgeon at the general hospital that before admission to the isolation hospital he had marked ankle-clonus, some rise of temperature, no retraction of the head or Kernig's sign, and that the knee-jerks were much increased.

CASE 2.—Male, aged 18, was admitted to the general hospital as a case of infantile paralysis and transferred to the isolation hospital as encephalitis lethargica.

Condition on Admission.—When admitted to the latter institution he had retraction of the head, Kernig's sign, no third nerve implication, no history of double vision, knee-jerks and other reflexes diminished, paralysis of the right arm, and a normal temperature. He also was in great distress with greyness of the face, his speech was normal, but he swallowed with difficulty. He had no mental symptoms or lethargy, and died after 12 hours from failure of respiration and with a clear mind.

The cerebro-spinal fluid was clear. The laboratory report was: No globulin reaction, no cellular alteration, no organisms present. Not a case of septic or tuberculous meningitis.

These patients came from different districts and from houses five miles apart and, as far as could be found out, had nothing in common. In the family of Case 2 a sister, aged 15, died in June, 1919, from typical encephalitis lethargica with profound coma. She was seen by me and I reported on the case to the Local Government Board. Since this girl's death this family has removed to another house about a mile away.

In addition to these, my attention was called to a third case which also terminated fatally in the cottage hospital of a town about seven miles away.

The patient was a female, aged 18, with a history of slight head injury a month previously and with a doubtful history of tuberculosis in infancy. She was ill for six days and had headache, some drowsiness and rise of temperature, but no third nerve implication. Her symptoms were much the same as in Case 2, and she, too, died from failure of respiration and with a clear mind. The cerebro-spinal fluid was clear and under some increased pressure, and the report was also indefinite. She was dead when the case was reported to me, so that I had no opportunity of examining her.

Commentary.

During the past 12 months there have been seven or eight cases of encephalitis lethargica in

these three districts. One of these was clearly incorrectly diagnosed; another was a child on a visit who remained for a day or so only and then returned home. The remainder were well-marked cases.

Whilst I ascribed these three cases to a "polio-encephalitis" of some sort I had great difficulty in the differential diagnoses. There were the following essential conditions to be kept in mind: (1) Epidemic cerebro-spinal meningitis; (2) poliomyelitis under various names, as "Heine-Medinische Krankheit," or the Heine-Medin syndrome, polio-encephalomyelitis, antero-myelitis, epidemic paralysis, &c.; (3) polio-encephalitis; (4) encephalitis lethargica, also known as acute infective ophthalmoplegia, epidemic toxic ophthalmoplegia, epidemic stupor, &c. As each of these four groups was a notifiable infectious disease, returnable to the Ministry of Health, each was presumably a separate entity.

Some 50 epidemics of poliomyelitis have been recorded since 1840, mostly in Scandinavia and the United States of America, and with very few in England; and although there is no essential difference in the classifications given by Medin and by Wickmann, Medin's report alone showed cases which could be described as "polio-encephalitis." Apparently there were none in the New York epidemics, nor were the epidemics followed by sporadic cases with symptoms like those of encephalitis lethargica.

It would seem that Landry's paralysis in an adult is always poliomyelitis and that whilst polio-encephalitis is rare, that rarity would not exclude it from the Heine-Medin group, especially when one remembers how the predominant symptoms of other epidemic diseases vary from epidemic to epidemic. Whether the classification of the Heine-Medin syndrome should be enlarged to include typical cases of encephalitis lethargica seems doubtful; on the other hand, it may possibly be later shown that some of the groups now included with that syndrome should rather be classed with encephalitis lethargica. A careful consideration of the Local Government Report No. 121, on Encephalitis Lethargica, does not help much, and leaves the impression that an attempt was made to mark off a new disease by excluding those cases with symptoms pointing to poliomyelitis. The differentiating factor was permanent extremity paralysis, which in my two cases does not help.

There is clearly a polio-encephalitis, with or without spinal symptoms, of the Heine-Medin group, and a polio-encephalitis without the lethargy of the new disease. Although stupor is present in 80 per cent. of the cases of the latter condition, it is often a late symptom, and hence would be absent in a case rapidly terminating fatally. Besides, the bulk of the cases of polio-encephalitis appear to be fatal in from four to six days. The symptoms obviously depend on the particular parts of the brain and cord implicated. The clinical picture in a given case varies rapidly from day to day, and unless there is time to observe permanent paralysis or definite lethargy, it is clearly impossible, in sporadic cases and apart from an epidemic, to distinguish between the two diseases. Histologically encephalitis lethargica belongs to the class of polio-encephalitic diseases: both are inflammatory in nature, the organisms stated to have been found are similar, and there is no real difference in the cerebro-spinal fluid; in fact, the two reports showed that the specimens varied little, if at all, from the normal. In poliomyelitis there is usually a difference, whilst in encephalitis, as a general rule, there are no appreciable changes, although occasionally changes are found similar to those in the former disease. In any case these two conditions suggest a relationship to one another like that of typhoid to paratyphoid fever. Both are transmitted by carriers, not themselves necessarily ill, and in both the infection is by way of the nasopharynx.

A CASE OF

TONSILLECTOMY IN A BOY WITH CONGENITAL HEART DISEASE.

By S. G. PAPADOPOULOS, M.B., B.S. LOND.,
LATE MEDICAL SUPERINTENDENT, MILLER HOSPITAL,
LONDON, S.E.

THE following case is interesting on account of its unusual character:—

The patient, a boy aged 15, was suffering from congenital heart disease (apparently a patent foramen ovale), being extremely cyanosed and poorly developed. He had very large tonsils, almost touching in the middle line, with attacks of bleeding from the surface of the tonsils and also from the posterior nasopharynx, discharging ears, and pigeon-chest due to obstructed breathing. I first saw him two years ago and suggested operation, not only for the improvement of his breathing and the ear discharge, but also as his only salvation, as repeated attacks of tonsillitis were making his life precarious. Since then he saw two or three throat specialists, who, owing to his heart condition, advised against operation. I saw him again in the middle of August. His condition was much worse; he had repeated attacks of bleeding and colds. The bleedings were due to general oozing from the surface of the tonsils and pharynx. Gargling with liq. fer. perchlor. and adrenalin easily stopped it.

Operation was again advised as his one chance, and was at once agreed to.

Operation.—The operation took place on Sept. 4th, 1924. Anaesthetic A.C.E. (very light). The patient took the anaesthetic very well, and the tonsils were enucleated and adenoids scraped. He bled moderately during and soon after the operation and vomited blood once. There was no bleeding between 8.15 and 10 A.M. At 10 A.M. sharp bleeding commenced from mouth and nose, and he vomited 6 oz. of blood. Adrenalin swabbing stopped the bleeding temporarily. There were no bleeding points to be tied. At 10.30 A.M. he bled again, and vomited half a pint of blood. At 11 A.M. a gargle of liq. fer. perchlor., 1 drachm to the ounce of water, stopped the bleeding at once. The fauces were examined, and there was no bleeding whatever. Clots were formed. Gargles were continued half-hourly. From this time on no bleeding took place from the seat of the operation. At noon he vomited half a pint of blood, which was repeated at 2 P.M. and again at 3.30 P.M. in large quantities. Pulse 116. By now he began passing pure blood per rectum. There was no bleeding from the nasopharynx, and I came to the conclusion that the bleeding was due to oozing from the mucosa of the stomach and intestinal tract. At 3.30 I gave him $\frac{1}{4}$ in. of adrenalin hypodermically, and at 4 P.M. he vomited a large quantity of blood. Things were looking very alarming, and I decided to try hypodermically an injection of coagulen Ciba. I gave him at 4 P.M. 5 c.cm., and the patient was allowed ice to suck. He slept until 7.30 P.M., when he vomited half a pint of blood and passed per rectum a similar quantity. Saline given per rectum was returned mixed with blood. I repeated coagulen Ciba 15 c.cm. hypodermically, and ten minutes later $\frac{1}{4}$ gr. of morphine. The effects were most gratifying. He slept soon afterwards, except for sips of water, until noon the next day.

Since then he made an uninterrupted recovery. He never vomited or bled by mouth or rectum after the second coagulen injection. The following night he had another $\frac{1}{4}$ gr. of morphine. He began to take fluids freely, and by the 6th his pulse fell to 92. On the 10th he was up and about in the room. His breathing is easy, he sleeps without snoring, and his ears are drying up. His colour is better, his heart regular, and his pulse normal.

Jan. 9th, 1925: The boy is now going to school; he has had no "cold" since the operation. He is gaining weight and looks much healthier.

Remarks.

The unusual type of hæmorrhage I attribute to the poor coagulability of the blood due to the mixing of venous with arterial blood. I had not before seen congenital heart disease or organic valvular disease in young people give trouble under careful anaesthesia. I was also struck by the almost magical action of the coagulen, and intend to try it again in any future case of intractable hæmorrhage. I propose also to put the patient on calcium lactate to prevent his tendency to bleed.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

JOINT SECTIONS OF MEDICINE AND ELECTROTHERAPEUTICS.

A JOINT meeting of these Sections took place on Jan. 16th, Dr. ROBERT HUTCHISON, President of the Section of Medicine, presiding, supported by Dr. STANLEY MELVILLE, President of the Section of Electro-therapeutics.

"ELECTRONIC REACTIONS."

Sir THOMAS HORDER, on behalf of himself, of Dr. C. B. HEALD, Colonel H. P. T. LEFROY, Mr. WHATELY SMITH, and Mr. M. D. HART, made a communication upon this subject. In his prefatory remarks Sir Thomas Horder thanked the joint sections for a liberal-minded decision to accept the communication which he described as "concerned with the procedure and results of an investigation of which the object was to determine, as conclusively as might be practicable, whether there be any valid basis for the claims put forward in respect of the so-called electronic reactions of Abrams (E.R.A.) or of any analogous technique allied thereto or developed therefrom." Other introductory points made by Sir Thomas Horder were, that the inquiry which he was now reporting upon had been confined exclusively to the "reflexophone" apparatus of Abrams and to the "emanometer" of Boyd, the latter being, he explained, not a variation of the apparatus of Abrams, but "a design de novo based on a different conception of the phenomena involved." He wished to thank Dr. W. E. Boyd, of Glasgow, for giving the fullest facilities for investigation, and, in referring to Dr. Boyd's work on the relation of certain electrophysical phenomena of homœopathy in special reference to the E.R.A., he wished for himself and his co-investigators specifically to emphasise that no recognition of homœopathic doctrines was implied as regards either fundamental principles or clinical methods.

Previous Critical Views.

Sir Thomas Horder then demonstrated upon the screen the emanometer of Boyd and the reflexophone of Abrams, the claims of Abrams being described as of a character to ensure reception by medical and lay critics alike with scepticism tantamount to hostility. He said that the essential features of the Abrams diagnostic technique were substantially as follows. "The specimen, usually a drop of blood on filter-paper, is placed in a box called the 'dynamizer' containing three electrodes; of these the two lower, on which the specimen rests, are electrically connected to earth, while the third, which forms part of the lid, is connected in series with three resistance boxes. The first of these is called the 'amplifier,' while the second and third are known as 'reflexophones.' From the second reflexophone a wire passes to another electrode placed in close juxtaposition with the forehead of a normal, healthy person standing on earthed plates facing west, and known as the 'subject' or 'medium.' Certain areas on the abdominal wall of this 'subject' are then percussed by the operator, and for each such area the first reflexophone is adjusted until the normal percussion note changes to 'dull'; the readings of the reflexophone corresponding to such changes of note are known as 'rates,' and these, taken in conjunction with the position of the abdominal area under percussion, are interpreted in terms of the pathological or other characteristics of the patient from whom the specimen was obtained. The 'intensity' of the disease is estimated by altering the second reflexophone until the reaction disappears and the percussion note resumes its normal character. The apparatus, as re-designed by Dr. Boyd and named the 'emanometer,' differs in several respects from that described above, although it equally involves—at present—the

use as a detector of a normal human subject standing on earthed plates facing west, or, more strictly, at right angles to the horizontal component of the local magnetic field. A receiving plate is connected through a variable inductance and a variable condenser in series therewith to an electrode strapped to the subject's forehead. The specimen—whether chemical or physiological—is carried in a holder, of which one side is earthed, and this holder may be moved nearer to or further from the receiving plate of the apparatus in order to measure the intensity of the reactions. Tuning is effected by varying the value of the inductance instead of by adjusting the first reflexophone or resistance box, as in the Abrams technique, but the processes of abdominal percussion are substantially identical in the two methods. An outstanding feature of the Boyd apparatus—as contrasted with that of Abrams—is the incorporation of earthed metallic screens which are claimed to eliminate contamination from external sources; these screens are made either of sheet copper or of copper gauze having a mesh of about 30 to the inch."

Sir Thomas Horder continued as follows: "A certain number of practitioners obtained, by sending specimens to Abrams for diagnosis, results which persuaded them that some at least of his claims were not wholly unfounded, and the technique accordingly spread until at the present time there are, it would appear, many hundreds of exponents of his diagnostic and curative methods in the United States of America alone. It is true that of these adherents all too large a proportion are of the variety known as 'advertising specialists,' but there has always been, and still is, a certain reputable minority who, whether they have adhered to the original Abrams apparatus, or like Dr. Boyd, have devised conspicuous modifications, have sought patiently and sincerely to elucidate the problems involved and to eradicate such errors as they have encountered. This fact, taken in conjunction with the importance of the issues at stake, should have sufficed to ensure for the technique a judicial and painstaking investigation and to save it from the bigoted and a priori condemnation in which, actually, critics almost exclusively indulged, and of which alone the majority appear capable. It would be idle to deny that Dr. Abrams constantly put forward the most startling claims on the slenderest evidence; that he persistently evaded test conditions; that he expressed himself in a jargon characteristic of charlatany; or that he had no scruple in selling or leasing to others, at high charges, apparatus crudely constructed and at best imperfectly developed. But all this, although indicating an unfortunate lack both of scientific method and of scientific conscience, is no justification of the manner in which the subject has been handled by critics. For the possibility should not have been forgotten that Dr. Abrams might, in fact, have lighted upon a discovery of genuine scientific importance and yet have elected to exploit it to the utmost for immediate advantage in preference to entering upon a prolonged, laborious, and financially unprofitable research. The sequence of events in the present case has been closely similar to the case of Mesmer, and it is at least certain that the methods of criticism hitherto employed have served mainly to create an atmosphere of bitterness and suspicion without contributing in any proportionate degree to the settlement of the issue. It is, indeed, not at all surprising that the ineptitude displayed has so alienated the sympathies of electronic practitioners that they have frequently refused to submit to the 'tests'—so-called—which have been suggested, although on the other hand their omission—speaking generally—to recognise the limitations of their methods or to suggest fair trials which they might be capable of satisfying is greatly to be regretted."

Sir Thomas Horder then briefly referred to the critical attitude with which various papers in this country and the United States received the claims of Abrams, and indicated that an investigation by the *Scientific American*, having been conducted by a committee on sound lines, had been taken as finally

adverse. The verdict of the committee was, he said, to find that the claims advanced on behalf of E.R.A. and electronic practice in general were not substantiated and had no basis in fact, and that the so-called electronic reactions did not occur and the treatments were without value.

The Present Investigations.

Sir Thomas Horder then explained the genesis of the new investigations which originated in the view of Dr. Heald, medical adviser to the Director of Civil Aviation, that, if there should be anything in the claims of the Abrams school an inquiry might with advantage be conducted on lines similar to those of a number of investigations which have been initiated in the Department of Civil Aviation during the past six years. Sir Sefton Brancker, Director of Civil Aviation, authorised a preliminary investigation, the result of which was that the Air Ministry, though maintaining a cordial interest, did not feel disposed to conduct an official research or to refer the matter for that purpose to the Medical Research Council. Dr. Heald then pursued his investigations as a matter of personal interest, when he found that much specialised knowledge outside the scope of normal practice made it necessary to enlist the services of Colonel Lefroy, head of wireless research at the Air Ministry, and Mr. Hart and Mr. Whately Smith, who are engaged in physical research work on behalf of the War Office and Air Ministry respectively. Sir Thomas Horder said that he had consented to act as chairman of a committee thus constituted. The work of that committee he defined as an inquiry under two headings, the first, purely physical, being the question whether the blood and secretions of a patient give out any form of energy which can be detected and measured by known physical means; the second being, what relation does any tuned and recorded "electronic energy" bear to known pathological conditions? He gave an account of the *prima facie* evidence which persuaded the investigators that the claims of electronic practitioners were not necessarily all ill-founded, but pointed out that a second phase was reached at the investigations by Dr. Boyd and Mr. Whately Smith in June of 1924.¹

Sir Thomas Horder then selected three cases of special interest as being of a sufficiently concrete nature to admit of reasonably succinct description, the purport being to show that the results obtained could not reasonably be attributed to pure chance, to ingenious guesswork, or to deception. Four series of tests were carried out, the results of which were summarised as follows: In the first series, 12 trials were successful and 8 were failures; in the second, 10 were successful and 2 were failures; in the third, 8 successful and 4 failures; in the fourth, 16 successful and 4 failures. Total: 46 successes and 18 failures out of 64 trials. It is easy to calculate the chances of these results being accidental, for if it is assumed—which the speaker found legitimate—that the demonstrator could not know by sight or by hearing the position of the screen, it is clear that his chance of giving by guesswork a correct answer in any given case is one-half. "Actually the chances are," said the speaker, "approximately as follows:—First series: 1 in 8 or 7 to 1 against. Second series: 1 in 62 or 61 to 1 against. Third series: 1 in 8 or 7 to 1 against. Fourth series: 1 in 216 or 215 to 1 against. Or, if the whole set of 64 trials be taken collectively, the chance of 46 successes or more being obtained by accident is about 1 in 3038 or odds of 3037 to 1 against."

Nature of the Problem.

"As evidence began to accumulate," Sir Thomas Horder continued, "the problem of how best to deal with the situation became increasingly acute. It is easy to condemn a novel and somewhat fantastic technique on *a priori* grounds, and it is not difficult

to establish a new discovery—even in the face of hostile criticism—if its phenomena can be easily reproduced and explained in terms of accepted scientific principles. But if in addition to their strangeness the phenomena be erratic and difficult to demonstrate and if their causes be in a high degree obscure, then special precautions must be taken in order to ensure a convincing outcome for the investigation. This was essentially the position which confronted the present investigators, and it will be desirable to give a few words in explanation of the reasons which determined their plan of action. The study of such phenomena as the so-called 'electronic reactions,' here considered, falls naturally into three distinct phases or aspects which may be referred to as demonstration, explanation, and interpretation respectively. In other words, there arises first the question of whether the phenomena under consideration occur at all; second, that of why they occur; and third, that of what significance they may possess. Now, the first aspect is of paramount importance in the earlier stages of an investigation of this kind; for provided it be shown beyond reasonable doubt that new phenomena exist there is not likely, in these days, to be any difficulty in ensuring an adequate study of their causes and their significance. But although this be true, there is no doubt that a demonstration supported by a reasonable explanation is likely to be more convincing and more readily accepted than a bare asseveration of facts which, however well these may be evidenced, must stand alone on their own merits. It was accordingly decided to conduct, in the first instance, a series of essentially physical experiments in order to determine whether the 'reactions' (i.e., the changes in the percussion note and the concomitant effects apparent only to the operator) were accompanied by any changes (e.g., in the electrical condition of the skin) which could be detected by physical apparatus of an ordinary type. And it was decided also to leave temporarily on one side all questions of the manner or degree in which the reactions, if any, might be correlated with disease or with any other physiological conditions of the persons from whom specimens might have been taken. It was thought that some relatively gross effects, similar, for example, to the change in skin resistance associated with the psycho-galvanic reflex, might be discovered, and that these would not only enable the existence of the phenomena to be demonstrated beyond cavil, but would also point the way towards the elucidation of their origin. Even in the event of experiments on these lines yielding negative results, the labour involved would not, it was decided, have been wasted; for if the reality of the phenomena were to be subsequently established a good deal of ground would have been cleared while, in the alternative case, it would not be possible for the 'electronists' to complain that any reasonable line of inquiry had been overlooked."

At this point the services of Mr. H. StG. Anson were requisitioned. This observer, said the speaker, was recommended by Faraday House as being exceptionally well qualified to undertake original work in experimental physics, and conducted experiments partly in London and partly with Dr. Boyd in Glasgow, over a period of some five months. He attempted to obtain instrumental evidence of some change in the electrical condition of the patient's skin concomitant to the variation of the percussion note and to obtain graphic records of the acoustical phenomena. Much of the work remained abortive, and in view of the negative results obtained

Crucial Tests

were embarked upon. Sir Thomas Horder continued:—

"In view of these considerations, it was decided to rely exclusively on tests of such a character that the value of the results obtained could be unequivocally computed by mathematical methods and to persevere with a series of such tests until it became apparent that their general tendency was either towards results

¹ Mr. Whately Smith's communication formed Appendix I, to the Report.

reasonably attributable to chance alone or else towards figures which could not rationally be ascribed to such causes.

The first test of this kind was carried out in London in May, 1924, with the co-operation of Dr. W. R. McCrae, assisted by Dr. Boyd. It took the form of an attempt to separate correctly 20 pairs of specimens of sputa taken from two patients chosen and approved by Dr. McCrae. Twenty specimens were taken from each patient by Dr. Heald and Mr. Whately Smith and were arranged by them in pairs and numbered according to an arbitrary key. Each pair contained one specimen from each patient, but there was nothing to indicate which was which. Control specimens were taken by Dr. McCrae. The outcome of the test was unfavourable to the technique, for of the results returned by the exponents 11 only were correct, while nine were wrong; which is just the kind of result which would be expected if chance alone were operative. In a memorandum addressed to the investigators, Dr. Boyd ascribed this failure to two main causes—namely, first that the screening arrangements then available at Dr. McCrae's laboratory were insufficient to ensure complete freedom from 'contamination,' and second, that the time required for examining, checking, and re-checking 40 specimens was so great that many of them became stale before they could be dealt with—a tendency liable to be aggravated by the necessity for avoiding undue fatigue on the part of operator and subject. He also expressed a desire that further tests of a slightly different character, but equally conforming to the requirements of the investigators, should be carried out in his own laboratory at Glasgow. To this suggestion the investigators willingly agreed, and on June 6th, 1924, Mr. Whately Smith visited Glasgow for the purpose. His full report is given in Appendix I., and the following quotation and abbreviated account of the tests is given here merely to show the kind of results obtained and the type of procedure adopted.

The first test consisted in discrimination between two apparently identical substances which were presented by the experimenter (Mr. Whately Smith) in such a way as to be indistinguishable by visual or other normal methods. Of 25 successive trials all were successful; the chance of this result being obtained by accident is 1 in 33,554,432.

Mr. Whately Smith's full account of this test runs as follows: 'The laboratory measures about 12 ft. by 6 ft. and is completely "screened" throughout as a precaution against radiation from sources other than the specimen under test; the floor is made of copper sheets, while the walls and door are covered with thirty-mesh copper gauze, all such surfaces being in metallic contact. Gauze screens are disposed about the room in various positions in such a way as to reduce the chances of interference by reflection to a minimum. In the end wall remote from the door is a window in which copper gauze takes the place of glass and which is provided with a hatch, about 12 in. wide by 18 in. high, fitted with a sliding gauze panel which can be raised or lowered by means of a chain and pulleys. Just inside this hatch is a narrow shelf on which test substances may be placed. This hatch communicates with an outer office in which drugs, papers, and other stores are kept, and it was from here that I conducted all tests, inserting specimens through the hatch as was required. After inspecting the laboratory and apparatus, the first test was attempted. From a group of about a dozen sterilised bottles and corks I selected two closely similar examples of each. One bottle was filled to a depth of about $\frac{1}{4}$ in. with a white granular substance believed to be "active," the other to an equal depth with a substance of identically similar appearance alleged to be "neutral." The corks were inscribed "sulphur 10 m." and "blank," respectively, in small characters. I satisfied myself by personal trial that it was utterly impossible for either the "operator" (Colin Campbell) or the "subject" (James Watson)—two Gallowgate boys—to distinguish the bottle visually when placed in position on the shelf just

inside the hatch. This was due to (a) the very dim light illuminating the bottles when in position; (b) the several thicknesses of copper gauze which in each case obscured the view; and (c) the close similarity of the bottles themselves. Dr. Boyd, Miss C. (his secretary), and myself then withdrew to the outer office and I inserted the two bottles "S" and "B" alternately through the hatch until the operator professed himself as satisfied with the tuning and as prepared to discriminate between the two substances. I then conducted a test consisting of 25 trials. For each trial I raised the sliding panel of the hatch, inserted a bottle, dropped the hatch and waited for the operator to say whether the reaction obtained was "dull" (corresponding to the "active" substance) or "clear" (corresponding to the "neutral" substance). The decision was practically always given within a second of dropping the panel, and on several occasions even before I had fully withdrawn my hand; I found it, in fact, difficult to keep pace with the operator. While this was going on, Dr. Boyd and Miss C. were, for the greater part of the time, just outside the room in which I was working, but continuously within sight. I was very careful to vary the order in which I presented the bottles and also to shuffle them frequently, so that no possible observation of my movements by operator or subject could furnish any clue as to which bottle would next be presented. After trials 8, 10, 12, 16, and 19, the operator asked, and was allowed, to check the two substances—that is to say, first the one and then the other was presented, and he was told which was which. After trial 10 the subject went out and washed in order to remove possible contamination.'

"The second and third tests," continued Sir Thomas Horder, "involved the selection and identification, in each case, of one specific substance from among a number of others; both were completely successful, and the chances of their results being obtained by accident were respectively 1 in 180 and 1 in 7776. These tests, like all the others, were conducted under conditions of control which appeared to be perfect. The fourth test was a repetition of the first. The operator gave 18 correct replies in 20 trials, and it seems probable that the two errors were due to faulty manipulation by the experimenter. But even if this be ignored, the chance of the actual result being obtained by accident is no more than 1 in 5518.

The fifth and last test was a screening experiment conducted on much the same lines as that already mentioned in an earlier section. Of 16 trials all were successful; the chance of this being due to accident or guesswork is 1 in 65,536. It was quite clear from these figures that the results obtained, whatever their true origin, could not reasonably be ascribed to the operation of chance alone. The only alternative to accepting the apparent phenomena as genuine was to assume either that Mr. Whately Smith's report was grossly inaccurate or else that he himself had been deceived by trickery—possibly pathological—on the part of Dr. Boyd or his assistant.² Both these possibilities appeared to the investigators to be exceedingly remote. It was, however, represented that an issue so important as this should not be allowed to depend on the unsupported testimony of any single observer, and the desirability of conducting a repetition of the tests described in order to confirm or refute these results as conclusively as possible was strongly urged. It was further pointed out that although the other investigators could deal adequately with the question of accurate reporting, it would be advisable to enlist expert assistance with respect to the possibility of fraud on the ground that no one who does not possess specialised knowledge of a high order is competent to express an authoritative opinion on such matters.

² It is desired specifically to emphasise the fact that at no time has there been the smallest suspicion or appearance of mala fides on the part of Dr. Boyd or any of his associates. The precautions taken were adopted purely as a matter of principle and to anticipate possible criticism.

The investigators accordingly approached Mr. E. J. Dingwall, M.A., and invited his coöperation in this aspect of the work. Mr. Dingwall is research officer to the Society for Psychical Research and has made a special study of the methods of deception and prestidigitatory technique associated with such matters as spurious 'clairvoyance,' 'billet reading,' 'spirit photography' and similar performances in which chicanery is frequently encountered and of all of which he possesses a world-wide experience. In the opinion of the investigators he represented the highest available authority on the subject, and they considered that although, strictly speaking, the only way of excluding trickery absolutely would be to repeat the tests in person using specially constructed apparatus and independent subjects; yet if an expert of Mr. Dingwall's calibre failed to detect any suspicious indication, they need feel no further uneasiness on this score, especially in view of the considerable bulk of collateral evidence with which they were already acquainted. Mr. Dingwall kindly consented to act as consultant in this matter and in due course accompanied Sir Thomas Horder, Dr. Heald, and Mr. Whately Smith to Glasgow on August 29th, 1924.

The tests conducted were substantially identical with those performed by Mr. Whately Smith in the course of his earlier visit, and the degree of success attained by Dr. Boyd was not less impressive.³ Mr. Dingwall carefully noted the arrangements and procedure and made certain suggestions as regards screening, &c., all of which were duly carried out without reacting in any way adversely on the success of the tests employed. It would therefore appear that, subject only to the theoretical reservation made above, all possibility of deception may safely be regarded as eliminated. The other investigators were entirely satisfied with the conditions of the tests and demonstrations given, and formed the opinion that no more convincing exposition of the reality of the phenomena could reasonably be desired.

Conclusions.

In view of the general considerations and concrete evidence cited in this paper, the signatories consider that the following conclusions are justified: (1) That certain substances, when placed in proper relation to the emanometer of Boyd, produce, beyond any reasonable doubt, changes in the abdominal wall of 'the subject' of a kind which may be detected by percussion. This is tantamount to the statement that the fundamental proposition underlying, in common, the original and certain other forms of apparatus devised for the purpose of eliciting the so-called electronic reactions of Abrams, is established to a very high degree of probability. (2) That no evidence justifying this deduction is yet available from the work of those who practise with the apparatus as designed by Abrams himself. (3) That the phenomena appear to be extremely elusive, and highly susceptible to interference, so that in order to obtain reliable results it is necessary to take the most elaborate precautions, particularly as regards the elimination of effects due to irrelevant objects. (4) That it would be premature at the present time even to hazard in the most tentative manner any hypothesis as to the physical basis of the phenomena here described.

It is impossible to emphasise too strongly that nothing in this communication is to be taken as implying that any correlation of those changes in the abdominal wall, referred to in conclusion (1), with pathological conditions has yet been shown, or a fortiori that any justification—physical, pathological, nosological, or clinical—exists for the direct use of either the Abrams or Boyd apparatus in diagnosis or treatment.

Bearing of the Conclusions upon Medical Practice.

Seeing that the electronic reactions of Abrams had their inception in the field of medicine, this communication will scarcely be complete without a reference to the question which will immediately be asked by many who read it: 'What relevancy have

the facts now demonstrated to the diagnosis and treatment of disease?' The electronic practitioner will probably answer, 'A great deal'; though he may protest that the demonstration has been entirely redundant; or, less ungracious, he may accept the demonstration as merely helping to establish further the claims he has already made. But in reality the answer must clearly be that the conclusions in this communication, as they now stand, are not in the slightest degree pertinent to the diagnosis or treatment of disease in any practical sense. That is not to say that they may not possess all sorts of potential bearings upon both of these things. But until the research is taken much further, and until either the explanation, or the significance, of the facts recorded shall be forthcoming, the application of the communication in the field of medicine is nil. At present there is no known correlation between the phenomena described and the fundamental facts of pathology, so that the value of this communication to the practising physician can only be negative.

As already stated, the present investigators have concerned themselves solely with the establishment, to their satisfaction, of certain basic facts. In view of the urgent need of an answer to the question 'Does anything happen?' they are satisfied for the moment with being able to say in effect, 'Something does happen.' Both the explanation and the application of the facts established await further investigation. Which of these will come before the other it is impossible to say, but until one of them arrives the mere statement of the phenomena here described gives no sort of sanction to any practitioner for using the Abrams method in practice. He may, of course, find a legitimate sanction elsewhere; for example, he may show results so consistently good as to justify him in continuing to use the Abrams apparatus in his daily work. But there is no evidence that even the most adept exponent obtains results so consistent as to justify him in doing more than experiment privately with the method. The present investigation clearly suggests one reason, and in itself a sufficient reason, why the electronist's⁴ results cannot but be inconsistent—namely, the absolute necessity for efficient screening as proved by Boyd. That it has not been found by electronists generally that such screening is imperative in order to eliminate errors, is in itself a damning proof that the haste with which the method has been carried into the consulting room has prevented any proper investigation of its limitations or of its potentialities. It seems probable that such developments as may take place on the clinical side are most likely to proceed from the methods initiated by Dr. Boyd, and still in process of elaboration by him.

By the term 'consistent results' is meant not the conformity of the electronist's diagnosis with the clinical and pathological facts of the case—concerning which reference will be made later—but some reasonable degree of conformity as between the results obtained by different electronists working upon the same material, and as between the results obtained at different sittings held by the same electronist, equally working with the same material. But this reasonable degree of conformity has been conspicuously absent in both cases. In the various efforts made by individual members of the present Committee to obtain evidence of 'something happening' by submitting tests of a simple kind to electronists willing to coöperate in this fashion—tests which it has not been thought necessary to specify in detail in this communication—lack of consistency has been very striking. On more than one occasion the electronist has admitted the discrepancies in his own results, and has on this account considered them unreliable and therefore to be disregarded.

There are in the hands of the committee details of experiments, carefully devised with a view to testing consistency of results, and submitted to exponents

³ A full account, said the speaker, is given in Appendix II.

⁴ This word is exclusively used, said the speaker, to refer to those who rely upon the apparatus and technique of Abrams.

of the Abrams method but with conspicuous failure. All account of these experiments has been omitted from this communication at the express request of the practitioner who was chiefly concerned pending further research. These belated misgivings may have been prompted by the knowledge of the imminence of a report of experiments carried out in such a way as to yield unimpeachable results. Here was an opportunity for some electronist, from whom the saving grace of the scientific spirit has not wholly departed, to come forward and acknowledge publicly the glaring inconsistencies which inevitably and constantly face him in his daily practice. But the opportunity has been missed. To turn king's evidence is never popular and oft-times unprofitable.

When electronists have been asked for an explanation of such inconsistencies as those referred to above they have sometimes attributed them to lack of expertness in their use of the methods and sometimes to new and startling discoveries as regards fallacies of dimensions so large that their very existence would seem, to any unbiased mind, to throw the whole thing back into the melting pot. But neither the modesty which may be supposed to dictate the first explanation, nor the fallacies referred to in the second, would appear to induce any such hesitation in actual practice. The practising electronist is not in the habit of prefacing his diagnosis by declarations of his own lack of skill, nor by any reference to such confusing facts as, for example, that unknown factors cause the same 'reaction' to be given by a carcinoma of the oesophagus and by pulmonary tuberculosis, or by simple gastric ulcer and by cancer of the stomach. No doubt any such prefaces, if systematically adopted, would quickly dispose of electronic practice altogether! It is obvious, therefore, that there is, at present, no proper sanction for the use of the electronic reactions of Abrams on the ground of consistency of results, whether as between different workers or as between the results obtained by the same worker at different times. But even supposing that such glaring discrepancies can be eliminated by proper attention to technical points such as the screening which Boyd finds so essential, and by the substitution of the Boyd apparatus for that of Abrams, sanction will still be lacking so long as there exists no demonstrable correspondence between the 'reactions' found and known pathological states. For patients do not suffer from 'reactions'; they suffer from anatomical and physiological disturbances. If it should be claimed by the electronist that the establishment as criteria of his 'reactions' is of greater moment to the patient than is the recognition of tissue changes and of the disfunctions of organs, then the onus lies with the electronist of stating adequate reason why the whole criteria of disease, as built up by the sciences of morbid anatomy and morbid physiology, should be revolutionised in this manner. This onus has never been accepted.

There is one other thing which may justly be regarded as a condemnation of electronic practice; electronists have been hard at work for some ten years; they have 'diagnosed' and 'treated' thousands of patients; yet no contribution to pathology, which is the bed-rock of medicine, has been made by any of them. Surely this is a significant fact, when it is remembered how epoch-making are the claims made on behalf of E.R.A.

To sum up. The conclusions arrived at in this communication leave the position of the practising electronist as scientifically unsound and as ethically unjustified as it was before. They give no sanction for the use of E.R.A. in the diagnosis or in the treatment of disease. Nor does there appear to be any other sanction for this kind of practice at the present time."

The PRESIDENT, after thanking Sir Thomas Horder and his colleagues for the report, put it to the vote of the meeting whether there should be a discussion upon it now or later, when the meeting decided against each alternative.

SECTIONS OF PSYCHIATRY, NEUROLOGY, EPIDEMIOLOGY, AND DISEASES OF CHILDREN.

A COMBINED meeting of these Sections of the Royal Society of Medicine was held on Jan. 13th, Dr. R. H. COLE, Vice-President of the Section of Psychiatry, in the chair.

Prof. EDWIN BRAMWELL opened a discussion on the MENTAL SEQUELÆ OF ENCEPHALITIS LETHARGICA.

He said that there had been considerable modifications in our views of this disease since the early cases were met with; the condition was now known to be much more varied and serious, with an onset that might be insidious and a course slowly progressive, remissions occurring months or years after apparent "recovery." It was difficult to draw the line between symptoms and sequelæ. While mental symptoms might predominate they were rarely if ever pathognomonic. Those which had impressed him most in adults were slow cerebration, mental fatigue, defective application and lack of interest in affairs. Recent memory impairment, while striking in one or two cases, was not a well-marked symptom on the whole; patients were usually unable to recall the early stages of their illness, but that was all. Great depression was unusual; there had been in his practice no cases of suicide, though two of his patients had spoken of it vaguely; usually they were complacent and did not worry over their condition. As an example of a common sequela, he cited a lawyer, previously a noted wit and after-dinner speaker, who completely lost his powers of repartee and his ability to tackle any new problem outside the routine of his work. This lack of spontaneous activity was characteristic; there seemed to be a general process of levelling down, the striking features of the individuality being lost. While disorientation and confusion were common at the outset, occasionally amounting to mania, and anxiety states might supervene on the failure to return to normal life, true psychoses were rare.

Encephalitis in Children.

In children Prof. Bramwell had met much the same phenomena, with the distinctions of a frequent failure on the moral side and a marked disturbance of sleep rhythm, the children being extremely restless at night. They lost the capacity for learning, although retaining the knowledge acquired before the illness. They lost interest in games, became careless about clothing and cleanliness, irritable, mischievous, destructive, dirty, cruel, obscene, untruthful, dishonest. Such changes in disposition were not commonly met with in the adult. While the mental symptoms were not generally adequate for a diagnosis, the history was usually sufficiently suggestive. A story of never having been well since an attack of "influenza" would be given, an influenza in which there had been no catarrhal symptoms and which had not spread to other members of the household; the patient would be said to have been drowsy or sleepless, with noisy respiration, so-called "chorea" or jerky movements, double vision for a few days perhaps, or an onset with an agonising pain for which no satisfactory reason could be assigned. The motor sequelæ might be very varied: Parkinsonian syndrome, some want of mobility of the face, some stiffness of trunk in turning, an unnatural pose of arm or hand, tremors and anomalous movements of all kinds would suggest the possibility of encephalitis lethargica.

Prof. ARTHUR HALL dealt with the subject from the aspect of the child patient only, these constituting, in his experience, some 40 per cent. of the cases. He pointed out that from this point of view the disease presented us with an entirely new picture, calling for new measures. The toxin selected those upper and upper-middle regions of the central nervous system which are not well-organised until adult life, and the damage to them produced a clinical picture which we had previously associated with adults rather than

with children. We had not been accustomed to observe sleeplessness for weeks on end in a young child, a case of paralysis agitans under 40, or homicide, suicide, and hooliganism in children. The main clinical aspect might be positive or negative. If the positive symptoms predominated there was tremendous feeling of fitness—euphoria; there might be continuous talkativeness, or the child be unmanageable and destructive. Delirium, if present, centred around the schoolwork or games, or something seen at the "pictures." The previously shy child would become bold and cheeky. These phenomena might be absent altogether or last for a few days, then giving place to death, or to a lethargic, drowsy, stupid condition. Prof. Hall compared these alternating effects to those of alcohol.

The Chronic Phases in Children.

The chronic phases Prof. Hall divided into four groups:—

1. The *Idiot*.—This presented no new problem, the higher centres were destroyed and the child irreclaimable. This type was only found if the onset had been in the first five years of life.

2. The *Parkinsonian* type, usually occurring after the tenth year. The mental defect underlying this was very hard to estimate because of the bodily disability. Prof. Hall thought that the greater the degree of pure Parkinsonism the less would be the mental defect found.

3. The *Apache* type.—This tendency was usually unmasked quite suddenly and unexpectedly in previously clever and good children. They became aggressive, quarrelsome, untruthful, dirty, and dishonest, and might commit homicide or suicide. Their number was not great, though they naturally called attention to themselves and were liable to exaggeration. They were mostly boys.

4. The *Difficult* or the "*Super-difficult*" child.—These formed the great majority, the borderline between them and the apache being ill-defined, and those cases lying near the border being peculiarly hard to deal with.

Prof. Hall showed a chart of the sleep hours of such a case, which manifested clearly the restlessness and activity of the night hours, the child falling asleep in the early morning and sleeping on long enough through the day to get the adequate amount of rest. He described the mental condition as one of asthenia, with lack of concentration and effort, and failure of the emotions, thus leading to a failure of parental control. The management of such a child might be compared to the riding of a half-broken colt with the reins suddenly cut. That they were amenable to really capable control was shown by the improvement in hospitals and country homes, and in the hands of competent parents. Any excitement tended to cause relapse. In regard to treatment, two rules could be enunciated: first, the community must be protected from the apache; and secondly, the difficult child must be saved from becoming an apache. For the latter, institutional treatment should be avoided, the child being given plenty of fresh air and good food, with organised play and exercise, while the mental training was very carefully graduated and supervised.

Encephalitis Lethargica and Intelligence.

Dr. F. C. SHRUBSALL gave an account of the records of after-histories of cases in the London school service. Two hundred and twelve cases under 15 years of age had been notified during 1924, and reports on 111 of these were to hand. Complete recovery was recorded in 26 only; in 44 there was change of conduct, in 40 sleeplessness, in 26 impairment of intelligence, muscular twitchings and tremors in 12, and ocular disturbances in 10. There was evidence of a rapid recovery of intelligence once the improvement had started, but the usual intelligence tests were difficult of application on account of the lack of concentration and the impossibility of ensuring the co-operation necessary. The rate of mental growth was found to be seriously retarded, especially if the child were less

than five years of age at the time of the attack. In older cases the growth of knowledge seemed to go on *pari passu* with a progressive loss, until finally the dementia won. Quite often a moral deterioration was unaccompanied by any diminution of intelligence, and masters would be very willing to take back employees who had been convicted of criminal offences, as they were satisfactory and faithful workers. The excitement symptoms might pass off under favourable conditions, but keeping the child in the limelight, or "baiting" by other members of the family might lead to secondary exacerbations. It had been noted that the disorder of conduct was usually one that might have been expected from a consideration of the heredity and environment, stealing, for instance, being met with in other members of the family, as if the disease merely unmasked or precipitated an innate tendency. The crimes committed were almost invariably done in the face of certain detection. It had been found that the irritability was reduced by carefully ordered industrial school life, but that the inclusion of such children in a community was disastrous for the other members, and any such institutions must be *ad hoc*. Regarded from the legal aspect there was no possibility of a successful plea of irresponsibility; they knew quite well the nature of the acts they committed; the only possible defence would be that of "irresistible impulse."

Dr. A. S. MACNALT, speaking from the epidemiological point of view, referred to the great increase in the number of cases, from 541 notified in 1919 to 1025 in 1923 and 4605 in 1924. He concurred in the difficulty of distinguishing between true after-effects and the persistence of the original infection. His colleague, Dr. Allan Parsons, had investigated some 250 cases of which 136 showed mental symptoms. There was mental impairment in 57; psychic disturbances in 47, drowsiness in 15, neurasthenia in 7, loss of memory in 6, and melancholia in 4. One hundred and twenty-one showed ocular palsies or pareses of face or limbs, and there was much weakness and exhaustion. In Dr. MacNalt's opinion the gravest symptom was the Parkinsonian syndrome. He agreed with Dr. Shruballs as to the kind of treatment desirable. The matter was under the consideration of the Ministry of Health.

The Nosology of Encephalitis Lethargica.

Dr. P. C. P. CLOAKE said that the symptomatology of this condition was so varied, striking, and bizarre that insufficient attention had been paid to a rational classification and explanation of the phenomena observed. He pointed out that many toxæmias might give rise to a state of delirium, although a constitutional nervous instability undoubtedly predisposed to its development. In encephalitis lethargica we had this process, and in addition a special selective action on the central nervous system. The state of toxic delirium accounted for the symptoms of impairment of apprehension, of the power of retaining mental impressions, memory defects, variability in mental capacity, and level of attention, going on to clouding of consciousness, with hallucinations and delusions and disorientation. As in all toxæmic conditions, these symptoms were worse at night. Due to quite another cause was the lethargy, resulting from a localisation of disease process in the mid-brain, and comparable to the symptoms produced by neoplasms of this region. Dr. Farquhar Buzzard had suggested that the mechanism of impairment was a blocking of the Sylvian aqueduct by swelling or scarring, with a resulting internal hydrocephalus. Dr. Cloake was of the opinion that the more we understood normal sleep the more we should understand this aspect of encephalitis lethargica. Either of these processes might be dominant. If the toxæmic syndrome were the more strongly marked there would be the excitement at night, while in the day the specific drowsiness would manifest itself in a milder form, it being easy to awaken the patient, who appeared then as if waked from normal sleep. If there were a diurnal delirium it was usually occupational and the patient could be

roused from it in a similar way. Coma, if it occurred, was probably toxic. This explanation of the symptoms also accounted for the sequelæ. The nocturnal restlessness was due to a mild subacute toxic state stimulating the cortex, and subsiding about 5 A.M. as such toxic states usually did. Mischievousness was really only hyperactivity, due to the removal of inhibitions, as in all mild intoxications. It must not be forgotten that the persistence of such behaviour might be partly habit, as shown by the improvement resulting from changed environment. Prolonged hot baths at bed-time were helpful in these conditions, lessening the toxæmia and drawing the blood to the peripheral vessels.

Delusions and confusion disappeared with the acute stage, but the brain did not at once recover from the damage, and what was left was a symptom-complex comparable to that of head injuries from any other cause. In the conditions resulting from head trauma there had been described the same difficulties in behaviour, the changes of character, impairment of concentration and memory, narrowing of mental grasp, loss of motor associations and failure of reasoning power, impairment of memory for recent and remote events, slowing of the stream of thought, and loss of inhibitions resulting in a life dominated by instincts, hitherto kept under control, which formed the characteristic sequelæ of an attack of encephalitis lethargica. In other cases the organic changes were not the most marked feature and the resulting picture was more characteristic of the specific lethargy, the lack of spontaneous activity, which might be present with or without impairment of intellect, the loss of psychic tone, which was pathognomonic, the apathy and inertia with good judgment and intellect, which might be compared to a permanent condition of half-sleep and which might exist without a Parkinsonian syndrome. There might also be adiposity and diminished sex activity possibly due to inadequate functioning or impaired absorption of the anterior pituitary. Lesions in the pituitary body had been recorded in encephalitis lethargica. True psychoses were accidents, and the mania, melancholia, and dementia præcox met with occasionally were not of the well-recognised types. The patient was often egocentric and hypochondriacal, but there was no real retardation of thought, and insight was always present. Delusions, if present, were weakly held, though persistent, and showed no systematisation or accretion, and the so-called "precocious dementers" had mental clarity and were accessible. They frequently showed basal ganglia lesions and were to be regarded as manifestations of organic cerebral disease.

Further discussion was adjourned until Tuesday next, Jan. 27th.

HUNTERIAN SOCIETY.

THE PERFORATION OF GASTRIC AND DUODENAL ULCERS AND AFTER.

At a meeting of the Hunterian Society held at the Mansion House, London, on Jan. 19th, Mr. H. W. CARSON occupying the chair, Mr. G. GREY TURNER delivered one of the Hunterian lectures of the session, taking for his subject the Perforation of Gastric and Duodenal Ulcers and After.

Mr. Turner began by exhibiting a table showing the results in all his cases during the past 24 years. The total number was 194, with 146 recoveries and 48 deaths. This was the gross number of perforations he had handled, and it included localised perforations, incomplete operations, and cases in which it was finally decided not to operate. The actual number of cases in which complete operations had been done during the same period was 147, with 124 recoveries and 23 deaths, the percentage of deaths thus being 15.64. Taking the 98 cases which were operated on within 12 hours of perforation, however, only eight deaths resulted, or 8.16 per cent. Of these, the

perforated gastric ulcers operated upon within 12 hours numbered 27, with three deaths, and the perforated duodenal ulcers 71, with five deaths.

He had selected this subject upon which to talk to a gathering largely of general practitioners because it was upon the general practitioner that the early diagnosis so essential to recovery depended. When a case was taken in hand reasonably early and was carried to a successful issue, the credit lay with the practitioner who had taken the responsibility and advised the operation, rather than with the surgeon who had actually carried it out. The all-important point was to get the case at a sufficiently early period. No new refinement in the technique of operation made anything like the difference that was made if only a short period had elapsed between the perforation and the surgical interference.

Importance of History.—The "Kissing" Ulcer.

He went on to speak of the extreme importance in these cases of relying upon the history. The onset was nearly always sudden, and it was of extreme value to take careful account of the evidence given by relatives and friends. On analysing his cases he was surprised to find how often these calamities occurred in people over 50 years of age. Among 50 gastric cases, six were in persons over 50 years of age, and among 143 duodenal cases, 40 were over 50. The fact that the symptoms occurred in a comparatively elderly person, therefore, need not deter a medical man from making the diagnosis. He also emphasised the frequency of the acuteness of the ulcer which perforated. He had, he said, long recognised how often the perforation which occurred was that of a second contact or "kissing" ulcer on the opposite wall of the stomach to that of a chronic ulcer. He felt convinced that this was an acute ulcer whose principal characteristic it was to perforate. It was not usually the chronic ulcer that perforated, it was the "kissing" ulcer.

Confronted with this calamity of perforation, the first duty of the surgeon was to save the patient's life. His figures with regard to immediate gastro-enterostomy suggested that this resort was apt to add to the mortality rather than to diminish it. Of 26 cases in which primary gastro-enterostomy had been done, 20 had recovered and 6 had died, a death-rate of 23.08 per cent., and of 98 cases without primary gastro-enterostomy, 81 had recovered and 17 had died, a death-rate of 17.34 per cent. His belief was that the best thing to do was to get the patient over the calamity of perforation, and then, if one was quite sure that a gastro-enterostomy was necessary for the cure of his trouble, to do this as a delayed operation before the patient left the hospital. He had done such delayed operation in 11 cases; no deaths had resulted. The average interval between perforation and gastro-enterostomy in these cases was just over 18 days.

Temporary Gastrostomy.

In very bad cases of general perforation he had tried temporary gastrostomy, and although the table of results might not appear to be very striking, he could speak about this procedure most enthusiastically. In many cases it had been of the greatest possible help. It must, of course, be understood that the cases in which it was done were very bad cases. Out of 147 operations for general perforations he had employed this measure 26 times, and in these 26 cases there were eight deaths, a mortality of over 30 per cent., but the average number of hours of perforation in these cases was 17. Another point of great interest was the question of irrigation of the peritoneum. He had started by being a most enthusiastic "washer," but later he altered his views. The death-rate as between cases irrigated and cases not irrigated in his own experience was not very different—about 16 per cent. in both instances. The percentage incidence of complications was 17 (irrigated) and 12 (non-irrigated). The death-rate also had to be read in conjunction

with the average period of perforation, which had been twice as long in the cases not irrigated as in the irrigated cases.

The Operation Problem.

The first problem that arose in connexion with the actual operation was the question as to where it should be carried out. In the great majority of cases it was better that the patient should be transported to a properly-equipped hospital, and except in a comparatively small number of cases this could quite safely be done. He thought that the surgeon should be content with the middle line of incision, and he must not be afraid to take hold of the stomach quite boldly. Very often the stomach was distended. Under these circumstances great help would be gained by passing a stomach-tube on the operating table; the stomach went down like a big balloon, and all that was then necessary was to stitch the ulcer. A thing which had astonished him was the way in which the dirty-looking material in the peritoneum was apparently absorbed without the slightest difficulty.

Complications.

With regard to complications, in his 147 cases of ruptured gastric and duodenal ulcer 23 developed major complications, and of these nine died. The complications were subdiaphragmatic abscess (five recoveries, three deaths), pneumonia and pleurisy (five recoveries, two deaths), pelvic abscess (one recovery, two deaths), gastric fistula (two recoveries, one death), pulmonary embolism (one death), and prolapse of intestine (one recovery). He also gave particulars of one remarkable case in which there had been repeated perforations. The first operation was done when the patient was aged 13, the ulcer being on the anterior wall near the pylorus. The second operation was at the age of 16, with the ulcer on the posterior wall, near greater curve. The third operation was at the age of 17, when there was a much indurated ulcer on the anterior wall, just in front of the hilus of the spleen. The fourth operation took place 21 days later. There was peritonitis due to rupture of an abscess just below the spleen. At the same time an anterior gastro-enterostomy was done. A fifth operation took place 29 days later for acute small intestinal obstruction. The patient made a good recovery, served all through the European war without trouble, and since demobilisation had had several obstructive attacks which were always relieved by medicine. Now, 15 years after the first operation and 10 years after the last, he looked and felt well, and could eat any food without trouble.

The lecturer gave a particularised account of the after-history of his cases. Out of 194 cases, 146 recovered, and of these 17 could not at present be traced; nine had been operated upon within the year, leaving only 120 cases for review. Of this number 81 were quite well, 19 had slight digestive trouble, 18 had had a further operation, two had recurrent trouble and required further operation, 17 had died (eight from some sequel of original trouble, and nine from other causes, without recurrence), and three were known to be well shortly after operation and were then lost sight of. As to the bearing of the type of ulcer on the question of recurrence, in a series of 31 acute ulcers the symptoms recurred in three cases, whereas in 44 cases of chronic ulcer 13 recurred.

Discussion.

The PRESIDENT said that Mr. Turner was to be congratulated upon getting his cases so early. When Mr. Turner stated that 75 per cent. of his cases were operated on within 24 hours of perforation, and more than 50 per cent. within 12 hours, he was amazed at the proportion. His own proportion was something like 15 per cent. in the first 12 hours.

Mr. JAMES BERRY said that Mr. Turner did seem to have a wonderful opportunity of getting these abdominal cases. This was largely due to the fact

that he and his colleagues at Newcastle had trained the practitioners in the neighbourhood to recognise gastric and duodenal perforations and send them without loss of time to the infirmary. With regard to drainage, his own feeling was that in the great majority of cases there was no need to drain at all: in a certain number of cases it was wise to put a single drain in the hypogastric region. It was equally essential that if that drain was put in it should be taken out very soon—the next day. He thought all surgeons would be agreed that irrigation was rarely to be done, though he remembered the days when surgeons used to wash out the abdomen thoroughly. As to whether gastro-enterostomy should be done after the original ulcer had been sewn up, his own practice had been not to do gastro-enterostomy, for it seemed to add a great deal to the risk of operation.

Mr. JAMES SHERREN commented on the change that had taken place in the type of perforated ulcer now commonly met with. Twenty years ago one found much more often than now an acute ulcer which had perforated, without any previous history. The majority of cases which perforated now seemed to be chronic and had given symptoms for many years. If an ulcer, whether of the stomach or duodenum, was chronic, he thought that, in addition to closing the perforation, the surgeon must at some time do a curative operation. The choice of the time would depend on the experience of the surgeon and the condition of the patient, and no rules could be laid down. The step taken would generally be a gastro-jejunostomy. His experience of cases which had refused gastro-jejunostomy had not been favourable; a good many of them had come into hospital with second perforations, and had died. No one, of course, would dream of doing a gastro-jejunostomy for the treatment of acute ulcer of the duodenum.

Mr. R. P. ROWLANDS said that cases which came to Guy's came as a rule very late; the main thing was to save the life of the patient, and he personally did not believe in doing a gastro-enterostomy as a routine. All these cases must be dealt with on their merits. If the operation of gastro-enterostomy became a routine, then there would be a high mortality, which would be quite unjustifiable. In a few cases in which it was not possible to close the perforation a gastro-enterostomy might be the only life-saving measure. Seeing that about one-quarter to one-third of the cases only required gastro-enterostomy, it seemed a pity to do gastro-enterostomy at the first operation; it was far better to watch and wait and do the gastro-enterostomy when the need of it was demonstrated.

Mr. GORDON TAYLOR thought that the mortality attending the catastrophe of perforation of gastric or duodenal ulcer had been greatly lowered, not by any particular modification of surgical technique, but by the comparatively early date at which, even in London, the cases were now received. Since the war cases of perforation had come under the surgeon's notice very much earlier than they used to do. With regard to the actual technique of the operation, in acute ulcers he confined his attention to sewing up the ulcer, but in the case of chronic ulcers, particularly juxtapyloric and duodenal ulcers, he did a simultaneous gastro-enterostomy. Mr. Turner had not mentioned one class of case, that of a simultaneous hæmorrhage and perforation, of which the speaker had seen two examples comparatively recently.

Mr. A. J. WALTON said that in his own experience, relating to 71 cases, nearly always these ulcers had been chronic ulcers. It was often said that the history was of little value, but in 36 gastric ulcer cases he discovered in all except two that there was a long past history, and the same was true of the duodenal ulcer cases. Then again, to confirm his belief in the chronicity of the ulcer, he found at operation the edge of the ulcer extremely indurated; in an acute ulcer, apart from perforation, there was never any induration. He had already published a series of 42 cases which were investigated in the post-mortem room of his hospital, and in all but one

it was reported that the ulcer on microscopic examination was manifestly chronic, and in the case of the exception it was not stated whether it was chronic or acute. It was his practice to perform gastro-enterostomy in most cases at the time. It added only about another ten minutes to the operation, and, as a general rule, he did not think it added to the danger.

Mr. T. P. LEGG said that he was usually content to suture the ulcer, and he did not perform a gastro-enterostomy; at any rate, he left the question of a gastro-enterostomy until a later date to see whether the patient needed it.

Mr. H. TANNER said that the wide distance one had to go with the sutures beyond the perforation was in favour of Mr. Walton's contention as to chronicity.

Reply.

Mr. TURNER said that it was quite likely that experienced surgeons might decide that in certain cases gastro-enterostomy was actually indicated and should be carried out at the primary operation; but he was sure that there would be fewer calamities if it was generally agreed that gastro-enterostomy, apart from exceptional cases, should be left to the second operation.

ROYAL COMMISSION ON LUNACY AND MENTAL DISORDER.

FURTHER SITTINGS.

(Continued from p. 1360.)

THE Commission resumed its sittings after the Christmas vacation on Jan. 13th, the Chairman of the Commission, Mr. H. P. Macmillan, K.C., presiding.

ALLEGED ILL-TREATMENT OR UNJUSTIFIABLE DETENTION.

The Chairman announced at the outset that the Commission had decided to undertake the judicial investigation of some cases of alleged wrongful detention and ill-treatment which had been selected by the National Society for Lunacy Reform, these involving serious allegations against particular individuals. It had been decided, he said, that both the persons making the allegations and those who met such should give their evidence on oath. The Commission, he added, were willing to receive and consider statements in writing by any person who might wish to bring information which might assist deliberations.

Dr. G. F. Barham (med. supt. of the L.C.C. Mental Hospital, Claybury) was examined. He said at the moment 2282 beds were occupied in that institution. The nurses were in the proportion of 1 to every 4.8 patients. During the last two years he did not think there had been cause to suspend any attendant pending investigation of a charge of wrong conduct. Three years ago he inquired into such an allegation, but the evidence did not support the charge. Only once in the past seven years had a nurse, a male, to be dismissed on account of ill-treatment of a patient. He said he favoured to some extent the employment of women nurses on the male side; under their influence the ward obviously became pleasanter and brighter, and by nature women made better nurses than men. In reply to questions, Dr. Barham said he favoured a scheme of co-operation between mental institutions and general hospitals by which periodic interchanges of staff might be effected.

He said he did not necessarily see all fresh patients as soon as they arrived, though one of the doctors did. He personally saw every new case within a few days of arrival; these were received into special admission wards, highly staffed. There was every facility for keeping patients until they had been completely examined and reported upon. In addition

to the usual history of patients supplied, the friends were written to, and information was received from a lady hospital visitor, who offered to visit the home from which the patient came. She was entirely a voluntary worker, and preferred to remain in that capacity. She was of very great assistance to him. She did not wear uniform. There was room for more such help. Her help was also most valuable when the time arrived for a patient to be discharged, for she found out to what sort of surroundings the patient was to go, and whether aid was needed for a fresh start in life. Asked as to the effect on a sensitive, educated patient of association with noisy patients, Dr. Barham said he had quiet reception rooms, and he would not subject a patient to such association. Shrieking, however, was much less frequent in a mental hospital than was commonly supposed. He added that a dentist attended twice weekly, and the institution could always procure the services of any specialist who might be needed. In reply to a question by the Chairman, Dr. Barham detailed the treatment carried on at the hospital, both mental and physical, remarking that the former included psychic analysis, and sometimes psycho-analysis. By constantly watching the patient and trying to rehabilitate the mind, one derived a good clue as to what was wrong. Small details, such as the manner of serving dinner and the arrangement of the ward, were regarded as important, for everything which tended to make life happier was a help. As soon as one of the doctors thought a patient was becoming convalescent, his (the speaker's) attention was drawn to him or her, and he gave such patient his personal oversight. In such a large institution he could not claim to know intimately many patients, but he could rely on his colleagues.

The Chairman asked him whether he favoured the separation of the administrative from the medical functions of the head of such an institution. Dr. Barham replied that it would be a very helpful thing if it could be managed, but he was fairly strongly convinced that it was impossible. Much of his routine administrative work he was able to delegate, and he had a large clerical staff. The idea of a responsible person being able to relieve the head of much administrative work and so enable him to concentrate on the medical work was capable of development. Division of responsibility, however, was a difficult matter. In answer to further questions, he said that some patients on going out might not have homes to go to, and in the solution of this problem the After-Care Association was of great value. Many times it was found that a patient, apparently recovered, on going again into the world unsheltered suffered a relapse. In the year 1924 184 patients were discharged from the hospital, 126 of them discharged recovered, 32 relieved and sent to the care of friends, 13 on trial, and one on trial had died. Twelve patients sent out on trial relapsed. Many patients received allowances on leaving the institution. A great deal of correspondence and trouble was caused by relatives and friends requesting discharge before patients were fit for it. A very considerable number of incipient cases if given early rest and appropriate treatment would, he was convinced, escape certification. If anything was developed along the lines of early clinics for these cases he hoped there would be a great number of places available; there should be liberty for patients to go where they wished for such treatment; and, of course, the Maudsley Hospital should be open to them. Asked about the effect of the "stigma" attaching to a mental hospital, the witness said that under the clinic system the mental department of a general hospital might come to be known as the "mad ward."

Asked by Mr. Micklem whether he thought it wise to have such large establishments as that at Claybury, Dr. Barham said he hoped that future institutions would not be built so large, though the Claybury Hospital was not out of hand. One catering for about a thousand patients was his idea. Discharges might occur of patients who had been inmates as

long as 20 years. Artificial feeding was sometimes necessary, and, as a rule, it was done without trouble. Dr. Barham was questioned about the bathing and meal-times of patients, as well as visitations, and in his answers he said that the tendency was towards the open door and window, and contrary to the idea that patients were irrevocably locked in. If a discharged person had a chance of employment and wished a certificate stating he was recovered, that was always readily supplied. In reply to Mr. Snell, M.P., he said that the employment of women nurses on the male side at Claybury was discontinued because it was a war-time measure, and when the men returned their posts were restored to them; also, structurally, Claybury was not designed for this. The Committee, however, had under consideration the construction of two villas, and he had recommended that these should be staffed by female nurses.

Replying to Sir Humphry Rolleston, Dr. Barham said it was necessary to fix the age of entry for female nurses at 18 so as to secure them before they were ear-marked for some other occupation. Somewhat above 25 per cent. remained to go through with their training. He was questioned by Sir David Drummond as to the lack of definite improvement in the recovery-rate of mental cases, and replied that he did not think the recovery-rate was an absolute criterion; patients were now treated in a more intelligent and a more human way than formerly, and much depended on the definition of "recovered." He added that he would like to see his own hospital linked up with a general hospital and attached to a school of medicine, and to have the coöperation of an outside staff. The further one proceeded with the investigation of these cases the more one felt the need for help. In answer to Sir Ernest Hiley, the witness said that not more than four or five of the patients in the institution had psycho-analysis.

MENTAL AFTER-CARE ASSOCIATION.

Miss Vickers, secretary of the Mental After-Care Association, said this body was formed in 1879, and was a charitable institution. Most of its funds were raised voluntarily, but recently boards of guardians subscribed, though there were no official funds. Last year the Association had touch with cases from 117 mental institutions, and was instrumental in sending cases for rest and change before resuming work to cottage homes, run by retired mental nurses who understood the work. Inquiry was made into the home conditions of patients. The help of the Association was invoked by mental superintendents, who informed the secretary of the imminence of a discharge, and then the machinery was set to work. Where necessary, grants to facilitate a re-start in business were made. Last year 1176 patients were relieved by the Association, which was now forming provincial branches. Miss Vickers said she had personally interviewed over 7000 patients, and always alone. Asked as to complaints, Miss Vickers said these were very few and trivial, and if only people who criticised would go and see they would realise how futile they were. Probably not more than 4 per cent. of patients made complaints, and only a very small proportion of that 4 per cent. complained of any ill-treatment. In the last 14 months only two people had refused the offer of a visit to their homes.

EVIDENCE OF THE BRITISH MEDICAL ASSOCIATION.

The sittings were continued on the day following, under the presidency of the Chairman, when evidence tendered by the British Medical Association was received, Dr. R. Langdon-Down being its chief spokesman. He was supported by Dr. J. W. Bone, Dr. F. H. Edwards, Dr. C. O. Hawthorne, Dr. E. W. G. Masterman, Dr. Christine Murrell, Sir Jenner Verrall, and Dr. G. C. Lord, the last-named in the capacity of assistant medical secretary.

The Chairman said the Commission proposed to include the Association's valuable memorandum on the subject in its proceedings. There were varieties

and degrees of mental ailment which did not necessarily need restraint. The document considered that the compulsory order should be the last resort, not the first. The definition of mental deficiency set out in the Mental Deficiency Act, 1913, seemed to include some states of what could be called mental disorder.

Dr. Langdon-Down said that unfortunately that Act endeavoured to set up a medical classification of those patients. Sir Humphry Rolleston thought the term "mental abnormality" should be replaced by "mental disability," as an abnormality might not be a pathological departure.

The next point discussed was the Association's view that in every case of certification two medical certificates should be required, the Chairman commenting on the extra total expense thereby entailed.

Dr. Langdon-Down did not think this, on a possible 15,000 certificates, would be an impossible amount. In some cases two certificates were very necessary, and how were exceptions to be made? To have only one put an undue responsibility on the certifying doctor. He added, in reply to further questions, that the Association considered that the usual medical attendant should be one of the certifying doctors. Any special standard, such as that of a holder of the Diploma in Psychological Medicine, would greatly limit the number of medical men available as signatories.

The Chairman pointed out the significance of the diagnosis on which the certificate was based, remarking that the specialist's diagnosis was regarded as the most valuable. He asked whether the curriculum of the medical student included a sufficient training in this branch of medicine, and Dr. Langdon-Down's reply was that he thought in most cases the student's course of training in this subject was sufficient. He asked that information on the point might be furnished to the Commission from university calendars. Asked by Sir Humphry Rolleston whether there was not at the present time great difficulty in getting general practitioners to certify at all, the witness said that was not because they distrusted their own capacity, but they were conscious of the risks to themselves in so doing. The profession considered that the protection to its members was inadequate, but it did not wish to under-rate its responsibility in the matter. The certifying practitioner, the Association thought, should enjoy the immunities of a witness in a court of law. The question at issue was, largely, one of the honesty of the practitioner.

The Chairman said that unless the professional man concerned could be trusted the system would break down. But to allow to the medical man the same immunities as a witness enjoyed would mean a considerable alteration in the law.

Dr. Langdon-Down replied that if the present law on the subject were allowed to stand it would certainly deter the medical man. After the first verdict in the Harnett case the Association received large numbers of letters asking for guidance in such matters.

The Chairman agreed that it seemed wrong that the doctor, for doing his duty in this respect, should be, as it were, placed in the dock to justify himself, instead of the onus of proof lying on the attacker; but it was a greater thing to ask for absolution from all possibility of an action.

Dr. Langdon-Down said the Association approved, in the main, the general principles of the Mental Treatment Bill.

On the question of the sending of a case requiring immediate attention to the workhouse—thereby rendering him a pauper—Dr. Langdon-Down said that if the accommodation and arrangement of workhouses were better there would not be so much objection to those institutions.

The Chairman said he thought some intermediate institution was the ideal, and the wards of the ordinary hospital might be used, though a separate section would have to be provided, and to this Dr. Langdon-Down agreed.

Dr. Masterman gave an account of the provision of infirmaries in London, remarking that if only the stigma could be removed, the accommodation for lunatics in the larger infirmaries of London was just what was wanted.

It was agreed that the evidence from these representatives of the B.M.A. should be continued at a later date to be arranged.

THE MEMORANDUM OF THE BRITISH MEDICAL ASSOCIATION.

The principal objects favoured in the Memorandum submitted to the Commission on behalf of the British Medical Association may be briefly set down as follows:

1. *To Meet Public Susceptibilities.*—In order to minimise the objections which prevent patients from accepting proper treatment at the earliest possible moment, it is proposed to avoid undeserved stigma by allowing less formal arrangements for suitable cases. It must always be borne in mind, however, the Memorandum adds, that the associations springing from any arrangements "will depend in the long run upon the actual facts and usage and not upon any verbal discretion or sympathetic intention."

2. *To Avoid the Need of Formal Certification.*—For mental patients whose symptoms, though acute, are likely to be short-lived, there is a hope that their recovery may render a formal reception order unnecessary. The Mental Treatment Bill of 1923 made a proposal for the temporary treatment of mental disorder without a reception order, the period to be limited to six months, with power to extend to a further six months. The Memorandum proposes to extend the voluntary boarder principle to cover all consenting cases and to make it applicable both to the 12 months of treatment and during convalescence if so desired.

3. *To Provide Opportunities for Voluntary Treatment.*—The provision enabling registered hospitals and licensed houses to receive suitable patients as voluntary boarders should be extended to county and county borough asylums. The system implies the consent of the patient and provides for care and treatment as long as necessary, thus avoiding or postponing the necessity for a reception order.

4. *To Arrange for Accommodation to Suit all Needs.*—Some sections of the population prefer public management, some private. There is a desire in the community generally that many patients should be treated otherwise than in public institutions. The existing veto on the setting up of new licensed houses should therefore be repealed or facilities provided for the treatment of patients in small numbers in private hands.

5. *To Secure Uniformity of Certification.*—Two medical certificates should be required by law in all cases, for submission to the judicial authority asked to issue a reception order.

6. *To Obtain Immunity for Medical Signatories.*—The Memorandum insists upon the medical certificate being definitely given the status of evidence, so that the protection which witnesses in courts of law are entitled to receive shall be extended to the practitioner who signs a certificate under the Lunacy Acts. Section 28, subsection 4, of the Act of 1890 runs: "Every medical certificate . . . shall be evidence . . . as if the matters therein appearing had been verified on oath."

7. *To Amend the Reception Order.*—The present urgency order might give way to a provisional order. It is clearly desirable that judicial authority should be obtained at the earliest possible moment for any measure which means the loss of personal liberty, and it should be sufficient for safety and convenience to limit the duration of an urgency order to three days. Such an order should be capable of extension for a further 28 days, at the expiration of which the patient must be discharged unless he is placed under a reception order or becomes a voluntary boarder. Experience suggests that many pauper patients who come under the 17 days period of observation get well and go home within this period.

8. *To Revise the Conditions of Voluntary Boarding.*—Permission in advance from the Board of Control or two members of the Visiting Committee appears unnecessary. Notice to leave should, in the interest of the patient, be extended to 72 hours.

9. *To Make Provision for After-care.*—The principle of permitting after-care and convalescent homes at the seaside or elsewhere in connexion with county and county borough mental hospitals should be recognised.

10. *To Ensure Unity of Central Administration.*—There should be a single administrative authority except in relation to property. Form 16 of the Lunacy Act, 1890, speaks of a person, entitled to payment from a public department, "by reason of mental disability unable to manage his affairs." This expression might be found useful to indicate the need for measures of control of the patient's property and affairs, not necessarily of his person, in place of the expression "of unsound mind."

The sittings of the Commission were continued on Jan. 17th.

ALLEGED WRONGFUL DETENTION.

The first of the cases of a specific charge of wrongful or improper detention was gone into, that of Mr. Hugh Wilson Holman, a consulting engineer and naval architect, aged 58. There were also present counsel for the doctors concerned and for Ticehurst Mental Home (Mr. Dickens, K.C., Mr. Croome Johnson, and Mr. Somerville, the last-named for the Medical Protection Society).

The Chairman said that when it was decided to take this case, it was thought right and fair to notify the persons concerned in the charges and criticisms, so that they might, if they so desired, attend and take part in the proceedings. The Commission decided to hear Mr. Holman's own personal experience only, and they would not announce their decision on any particular case inquired into in this way; the evidence so adduced would form part of the material upon which the Commissioners would ultimately base their report and such recommendations as they might make.

Mr. Dickens, K.C., on behalf of Dr. Percy Smith and Dr. Porter Phillips (who were present), asked that the specific charges against his clients might be formulated in writing, and stated that it would be necessary for him to go into the whole of the facts and call rebutting evidence from a number of witnesses. There was also the important matter of the expense of the proceedings.

Mr. Somerville pointed out that when the case of Mr. Holman was tried at the High Court, Mr. Justice Sankey, in his judgment, said he found not only that the authorities at Ticehurst were not negligent in acting as they did, but that they would have been negligent if they had released the defendant, under the circumstances. He, the speaker, therefore submitted that it was not fair to bring the doctors again to hear the same charge, nor profitable to hear evidence on which a judgment had already been pronounced in another place.

Mr. Stewart, who explained that he was briefed by Mr. Holman, intimated that there were many cases of the kind which could be brought before the Commission, and he called for the production of any documents which were or might be required to elicit the truth.

The Chairman said the Commission's difficulty was increased by the fact that the case had already been minutely examined in a court of law and judgment pronounced upon it. There was some embarrassment in dealing with concrete cases at all, because such hearing involved the mention of the names of particular persons. Yet it was felt it would not be proper to deprive critics of the existing system of the opportunity of putting forward some cases which they wished to have investigated; and the public would have the chance also of hearing any evidence which might be brought by way of answer.

Mr. Holman was then sworn, and examined by Mr. Stewart, who took him through his written statement, of which the following is a brief summary. In October, 1914, he suffered severe internal injuries as a result of an accident, and on recovery he took a post as hon. secretary to a Red Cross Hospital, and remained in the position two years. He then contracted pneumonia, and was taken to the house of a doctor in Croydon, where he became so ill that day that night nurses were necessary. In December, while there, he was certified and sent to Moorcroft though, he averred, his mental condition was quite sound. He transacted a good deal of business, saw a number of people, wrote letters, and kept a diary. A doctor came to see him, took a specimen of his blood, and, it appeared, reported a positive Wassermann reaction, but subsequent trials (five) were negative. At a later stage he declared he had never had any venereal disease whatever. A result of the report of a positive Wassermann was that he was declared to be a sufferer from G.P.I. He detailed visits of Sir Maurice Craig, Dr. Percy Smith, and Dr. Stoddart. He was driven quite unsuspectingly to Moorcroft, and on arrival there first learned that he was a patient in an asylum from the appearance of an old man, who came and sat down in an aggressive sort of way, and on being asked what he wanted said he was there to look after him, Mr. Holman. He then asked, "I am in an asylum, then, am I?" and the reply was, "Yes, you are in an asylum all right, and it will be very difficult to get out." He took that as a sort of challenge. On his first admission to the institution he was treated with considerable courtesy. He was seen by a special visiting justice appointed by the Uxbridge Bench, a grocer, who obviously knew nothing about lunacy. If he had had the opportunity of challenging the allegations on which he was incarcerated, he would have welcomed it. He said he was allowed to go into Uxbridge occasionally with an attendant, who often left him by himself. The witness alleged medical neglect when he had pneumonia and a relapse of his jaundice; he was, he said, left entirely to the head attendant, who was medically untrained. A surgeon was sent for to operate, but he did not do so, as he, the patient, was said to be suffering from general paralysis of the insane. After being in bed about a month he gradually regained strength. On the night of Feb. 8th, 1917, he escaped from the institution, and he sought out a doctor, who certified that he was fit for light duty, he having told the doctor that he was invalided out of the Navy and wished for an examination. He was retaken in Chancery-lane three days after his escape. This certificate was taken from him, and he was placed in one of the refractory wards. He took every possible legal step to secure his release, but without result. In January, 1917, he was transferred to Ticehurst, where he had only a cursory examination; all his protests against being detained were ignored. He determined to take the first opportunity of escaping from Ticehurst, and did so on August 28th, 1917, and hid for a fortnight, communicating afterwards with his solicitors to protect his interests and take means for obtaining redress. On representation to the Master in Lunacy, who was alleged to have expressed his dissatisfaction at the treatment, the witness's estate was released in his favour.

At the conclusion of Mr. Stewart's examination of the witness, Mr. Dickens, K.C., in cross-examination, asked whether he did not think he was at one time a menace to himself or others. The witness replied that he had not been a menace at any time, and he certainly had never been insane. He considered that the origin of troubles such as his was, that doctors were interested in private asylums, living as they did on fees derived for getting people in and out of those institutions. He considered that medical men should look upon themselves as members of a priesthood, holding aloof from the world's corrupt practices.

The Commission adjourned until Jan. 26th.

Reviews and Notices of Books.

RHEUMATIC HEART DISEASE.

By CAREY F. COOMBS, M.D., F.R.C.P. Lond.
Bristol: John Wright and Sons, Ltd.; London:
Simpkin, Marshall, Hamilton, Kent and Co., Ltd.
1924. Pp. 376. 12s. 6d.

THIS valuable monograph appears at a time when investigators in all countries are looking for a lead which will help to solve the problem of rheumatic heart disease. Dr. Carey Coombs during the past 20 years has given much time and thought to the study of this disease. Many articles have appeared under his name dealing with this subject, and these have been accepted by the profession as notable contributions to medical science. He writes from a wide experience which includes clinical observations made on a large group of patients, children and adults, extending over many years. In this book bacteriological investigations together with histological and pathological studies have been carefully recorded, and the chapters on diagnosis, prognosis, and treatment are dealt with from the practical viewpoint of after-history returns. Dr. Coombs is in complete agreement with Dr. F. J. Poynton, who contributes an introduction to the book, that the exciting cause of rheumatic fever is the streptodiplococcus first described by Dr. Poynton and Dr. A. Paine. To those familiar with recent transmission experiments in America, which offer strong evidence against the strepto-diplococcus hypothesis as the specific agent of the disease, the argument of the author in support of his view will appear unconvincing. In the chapter on physical signs, those structural changes in the valves and heart muscle which are recognised clinically by the usual methods of palpation, percussion and auscultation are described in detail. The author is not always on safe ground in his interpretation of these abnormal signs. There are certain adventitious sounds which are not so easy to explain as we are led to believe, nor for practical purposes is it essential to conclude from these signs that certain pathological changes exist. He takes the view that because a systolic murmur is sometimes absent in mitral stenosis, mitral regurgitation is not present in these cases. One could as easily argue that a systolic murmur is not a sign of mitral regurgitation. There are those who hold that mitral stenosis is always associated with mitral regurgitation, and as a systolic murmur is so often absent in this type of valve disease, it is fair to assume that the quality of such a murmur is an unreliable guide in the diagnosis of organic valve mischief.

Interesting facts emerge from the study of 600 to 700 after-history records of patients kept under more or less close observation over varying periods of years. The percentage of cases which could not be traced is small considering the difficulties associated with this type of research. The evidence furnished by this investigation has increased our knowledge of prognosis in rheumatic heart affections, and has enabled the author to write a valuable chapter on the treatment of this crippling disease.

BIOCHEMISTRY AND HUMAN PHYSIOLOGY.

Fundamentals of Biochemistry in Relation to Human Physiology. Second edition. By T. R. PARSONS, B.Sc. Lond., M.A. Camb., Demonstrator in Physiology in the University of Cambridge. Cambridge: W. Heffer and Sons. 1924. Pp. 295. 10s. 6d.

Mr. Parsons in his little volume gives the student a summary of elementary biochemical facts. In this edition he has included Werner's views upon the

formula for urea, and insulin is dealt with more fully than in the previous edition. Everywhere the descriptions are accurate, clear, and up to date, and we feel sure that they will be appreciated by the student. The difficulty of adopting a style agreeable to all is well known. Whilst a precise, cold analysis of facts, followed by a judicial summing up appeals to some, others may be more pleased with a lighter mode of expression. This little book is written in what might be called the "chatty" style. Quotations from some classical source head the chapters, and the Greek characters which adorn many of the pages may be out of place in a book for students. In essentials, however, the book is admirable.

THE PNEUMOCOCCUS AND PNEUMOCOCCAL INFECTIONS.

By L. COTONI, C. TRUCHE, and Mlle. A. RAPHAEL. English edition by D. S. PAGE, M.A., M.B., D.P.H., Assistant Pathologist to the City of London Hospital for Diseases of the Heart and Lungs, Victoria Park; and EVA MORTON, M.R.C.S., L.R.C.P., late Assistant Medical Officer, Grove Hospital, Tooting. London: John Bale, Sons and Danielsson. 1924. Pp. 218. 16s.

THE original French edition of this book appeared some 18 months ago and British readers now possess the advantage of a well-prepared English edition. The work is divided into three parts, the first dealing with the bacteriology of the pneumococcus, the second with the habitat of the pneumococcus and diseases of pneumococcal origin, and the third with the treatment thereof. Of these three sections the first is the most interesting and original. The authors have encountered the difficulties which beset all bacteriologists in defining the really essential unvarying characteristics of the true pneumococcus, and on the whole they incline to the four tests of non-motility, absence of spores, presence of a capsule, and staining by Gram's method as the four most dependable means of bacteriological diagnosis. Probably most laboratory workers will agree with the opinion expressed, that when a wrong diagnosis is made it is usually in mistaking a pneumococcus for a streptococcus. Several new media are described for the cultivation of the organism, the basis of them being Chapoteant's peptone which contains albumoses and peptone. To the use of this preparation the authors ascribe their success in carrying on subcultures indefinitely with medium T, a peptone water containing salt and glucose (pH value varying between 7.2 and 7.5); furthermore, with a modification of this medium in gelatin the authors have been able to keep pneumococcal cultures alive in the ice chest for many months. Solubility in bile the writers do not regard as an altogether reliable test. With regard to pathogenicity tests, they advocate isolation of the pure culture first rather than the injection of the original pus or sputum into animals.

Undoubtedly the most important—and at the same time the most difficult—section in this part of the book is the long section dealing with the subjects of immunity and agglutination, and the translators are to be congratulated on the careful way they have rendered this intricate portion into English. Many interesting points are raised. In the hands of these workers living cultures of a virulent strain of pneumococcus proved to be an unsatisfactory method of inducing active immunity in animals, whilst dead cultures of a non-virulent strain was practically devoid of antigenic properties. A killed virulent culture generally conferred immunity against a variable number of strains and, broadly speaking, the antigenic power of the pneumococci tested varied with their virulence. In this way a multivalent serum could be obtained. A method for standardising a unit of virulence in animal experimentation is also described. In the second part of the book, dealing with the habitat of the organism and diseases of pneumococcal origin, a critical discussion is included on the paths of infection in pneumococcal

diseases, notably pneumonia, on infectivity and contagion generally, and on the possibility of pneumonia carriers; whilst the crisis in pneumonia and the mechanism of its production is considered at length. Part III., on the treatment of pneumococcal diseases, is deliberately confined by the authors to specific immunological forms of therapy, and no attempt is made to discuss the ordinary palliative treatment of clinical medicine. After experience of serotherapy, the authors write of antipneumococcal serum: "We do not imagine that the preparation of the serum has been brought actually to the point of perfection, or that it is always administered by the best route and in sufficient quantity, and only to cases in which its use is justified. It would be injurious to the method to ascribe to it successes which are not due to it, but we firmly believe that in a number of cases the serum is definitely beneficial." With this careful estimate most English workers who have used serum would probably agree.

The English translation is a lucid, accurate, painstaking piece of work. All references in the extensive bibliography have been confirmed and the list brought up to date by the inclusion of references to work published since the appearance of the French edition. The translators have also wisely adjusted the loose terminology existing in the description of the types of pneumococci, so that the erroneously named Type IV. receives its proper designation Group IV., inasmuch as it is not, in reality, a type but a heterogeneous collection of organisms of the pneumococcus class.

PEDIATRICS FOR NURSES.

By JOHN C. BALDWIN, M.D., Lecturer in Pediatrics, Johns Hopkins Hospital School for Nurses. New York: D. Appleton. 1924. Pp. 261. 7s. 6d.

THE amplification of the curriculum of nursing studies which has taken place in recent years has resulted in the need of considerably more detailed text-books. This need is well provided for by this book, in which Dr. Baldwin has embodied several courses of lectures to nurses at Johns Hopkins Hospital. The author emphasises the fact that one of the principal duties of the nurse is to observe, and he has provided a text-book which presents a fairly detailed description of the external signs of disease in children. The instructions for feeding and management are lucid and concise, and essentially practical. A considerable portion of the book is devoted to acute disease, the exanthemata being described somewhat fully and illustrated by charts. This work does not completely cover the syllabus of the General Nursing Council in this country—rheumatism and chorea, for instance, are not included—but the book as it stands is so admirable that it may be strongly recommended to nurses as a supplement to a general text-book of nursing.

ORTHOPÆDICS.

Die Amputationen und Exartikulationen unter besonderer Berücksichtigung des Kunstgliederbaues. By Dr. TH. KÖLLIKER, Professor of Orthopædics. Leipzig: J. A. Barth. 1925. With 39 illustrations in the text. Pp. 68. 2.70 gold marks.

THIS brochure is intended for surgeons and students. It may be of value in Germany to those who cannot have access to other or larger works on its subjects, but as it consists of little more than general considerations and gives few details it can be of little use to the medical man who wishes for information on the prosthetics of a hip-joint amputation—to take only one instance. But one artificial limb for the lower extremity is illustrated, and very few arms, the only one for above elbow amputation being the Carnes' arm. In his preface the author recommends Schmieden's and Gocht's works to his readers. We endorse this recommendation, for Dr. Kölliker's pamphlet will hardly satisfy their needs.

INTERNAL SECRETION AND THE DUCTLESS GLANDS.

Third edition. By SWALE VINCENT, M.D., F.R.S., F.Z.S., Professor of Physiology in the University of London, Middlesex Hospital Medical School. London: Edward Arnold. 1924. Pp. 463. 25s.

In adding a selected bibliography to this third edition the author has done a wise thing. There is also added a good deal of matter dealing with the pancreas and insulin, with the reproductive organs and the question of rejuvenation, and a short chapter on organotherapy. Prof. Swale Vincent takes up a conservative attitude with regard to the latter, and also towards "the whole fabric of vagotonia and sympathicotonia, so dear to the credulous physician." The book is full of valuable information.

AIDS TO SURGERY.

By JOSEPH CUNNING, M.B., B.S., F.R.C.S. Eng., Surgeon to the Royal Free Hospital; and CECIL A. JOLL, M.S. Lond., F.R.C.S. Eng., Surgeon to the Royal Free Hospital and Lecturer on Surgery and Operative Surgery at the Royal Free Hospital Medical School. London: Baillière, Tindall and Cox. 1924. Pp. 434. 4s. 6d.

A VOLUME which can count five editions and many reprints has reached a secure point of reputation. Criticism would be superfluous were it not that, in a subject so fluid as surgery has shown itself to be, only constant revision can possibly keep up to date such a volume as "Aids to Surgery." The authors have succeeded in keeping abreast of modern methods and in maintaining the high standard of previous editions. The volumes of the "Aids" series are not intended to be exhaustive, but they help the student to epitomise his knowledge and to arrange it in an orderly manner. The student who thus fairly uses the present volume will undoubtedly find it of real value, using it as a skeleton into which he can build the knowledge he has gained. The student who uses it unfairly as a text-book will, we sincerely hope, meet at the hands of his examiners the retribution he justly merits.

We have only two suggestions to offer: One, that the admirable preface to the first edition, acknowledging the great text-book of Rose and Carless as the basis of the epitome, should be replaced; the other, deeply though we should regret the loss of such a landmark, that the heading of Chapter XXXII., which deals with the whole of abdominal surgery, should no longer be "Injuries of the Abdominal Walls."

INTELLIGENCE TESTING.

Methods and Results. By RUDOLF PINTNER, Ph.D., Professor of Education in Teachers' College, Columbia University. London: University of London Press. 1924. Pp. 406. 7s. 6d.

ONLY a few months ago a report on psychological tests was issued by the Board of Education, in which a general survey was attempted of the work done so far on this subject. Now, from the other side of the Atlantic comes this book with a somewhat similar aim from Prof. Pintner, already well known as the joint author of certain intelligence tests of the performance type, suited for application to those who for any reason have difficulty with the use of language, such as the deaf, the immature, and the foreign-born.

The book is designed for use as a text-book by students of the subject, and as such marks an epoch in its history. After a short historical sketch and a rather inadequate discussion of the nature of intelligence, the author gives an outline of the chief tests now in use. This outline is necessarily abridged

and requires to be supplemented by study of the literature referring to each scale, of which a very complete list is provided. The largest section of the book deals with the results of the application of the tests to certain definite classes—the feeble-minded, the delinquent, the school-child and college student, the super-normal, the deaf, the blind, the employee, and the specifically American problems of the Negro and the alien immigrant. On the whole the judgments expressed are well-balanced without the enthusiastic and uncritical dogmatism which marred some of the earlier American literature on intelligence tests. There is candid recognition of the fact that interpretations of results must be carefully guarded. In dealing with the feeble-minded, Prof. Pintner, as a psychologist, naturally favours a psychological diagnosis by mental age, and suggests that those whose defect is on the side of temperament and character should be classed as "psychopathic." The statutory English definition of feeble-mindedness, however, compels us to base our diagnosis on "social incompetence," which may be due to either or both of these causes. One can readily sympathise with his summary dismissal of the idiots savants of the older medical literature as not idiots and "far from being savants."

Dr. P. B. Ballard, in an introduction to this English edition, pays tribute to Dr. Pintner's "honourable part" in the development of the subject of the book.

JOURNALS.

ANNALS OF MEDICAL HISTORY. September, 1924. New York: Paul B. Hoeber. \$2.50.—Among the papers in this number the most noticeable are A New View of Elisha North and His Treatise on Spotted Fever, by Dr. F. L. Pleadwell; the Siamese Twins of Espanola, by A. P. Chavarria and P. G. Shipley, being an account of the first known post-mortem examination in the New World; and An Unpublished Letter of Sir Thomas Browne, by Dr. E. Moschowitz. Elisha North (1771–1843) was a practitioner who was in advance of his time. He preached and practised moderation in bleeding and in the excessive use of mercurials. He laid stress upon the importance of good nursing and was one of the first medical men in America to advocate vaccination. However, he had his weak side, a side which is shown by a manuscript examined by Dr. Pleadwell. This consisted of notes made by North for a second edition of his "Treatise on Spotted Fever"—i.e., epidemic cerebrospinal meningitis. In this MS. North expresses the view that spotted fever and cholera are both manifestations of one disease, which he calls congestive asthenia. Despite these views his treatment of spotted fever by stimulation instead of copious bleeding and sweating was very successful.—The paper on the Spanish "Siamese" twins is chiefly noticeable for the reason that the post-mortem examination was carried out mainly for the purpose of deciding whether the twins had two souls or one and the decision was in favour of the former hypothesis.—The letter of Sir Thomas Browne fills up a gap which has hitherto existed in Browne's correspondence as known up to now. In the autumn of 1658 Mr. W. Dugdale (afterwards Sir William Dugdale) wrote to Browne for information about the draining and embanking of fen country. On Dec. 6th, 1658, Browne writes to Dugdale promising him the information in a few days, and the MS. which came under Dr. Moschowitz's notice is the letter in question, dated Dec. 11th. Dugdale embodied most of it in his work, "The History of Embanking and Draining, &c." The letter, of which a facsimile and transcript is given, is in Browne's best style.—Mr. Warren R. Dawson, F.R.S., contributes some medical notes from Herodotus, but he has omitted one of the most interesting, namely, the passage in Book II., Chapter 95, about the Egyptian fisherman's use of a mosquito-net.

THE LANCET.

LONDON: SATURDAY, JANUARY 24, 1925.

POLIO-ENCEPHALITIS.

In another column Dr. E. A. B. POOLE, medical officer of health for Taunton Rural District, has recorded two or three cases of acute and fatal nervous disease occurring recently in his area, and has assigned to them a tentative diagnosis of acute polio-encephalitis. At the same time he has expressed dissatisfaction with the term, and is evidently conscious of no little confusion in dealing, as a medical officer of health, with a disease notifiable under Ministry of Health regulations and yet not apparently conforming to what is described in the publications of that Ministry. We are not surprised at the difficulties encountered by Dr. POOLE, nor, indeed, at his seeming failure to derive diagnostic help from certain Government reports.

Etymologically, polio-encephalitis stands merely for inflammation of grey matter in the brain, and quite lacks topographical and pathological specificity. Any inflammatory process invading grey matter is in reality a polio-encephalitis. The disease usually designated epidemic encephalitis is not defined thereby, nor would it be by applying to it the former expression, for encephalitis is as non-specific as polio-encephalitis, while the affection does not occur solely in epidemics. Still less is it adequately labelled as lethargic encephalitis, since lethargy may be altogether absent from the clinical picture. There are, as is well recognised, types of this disease in which the unknown virus exhibits a tendency to locate itself in certain collections of grey matter in the base of the brain; the numerous examples of post-encephalitic Parkinsonism that are seen to-day furnish proof of this contention, since there is good pathological evidence to attribute the symptoms to the incidence of the toxin or organism on the corpus striatum and its efferent systems. Conceivably, therefore, we might speak of an epidemic polio-encephalitis. On the other hand, however, polio-encephalitis has for years been the accepted terminology for a comparatively rare invasion of certain mesencephalic or pontine nuclei notably as a result of persistent alcoholic excess (Wernicke's polio-encephalitis superior hæmorrhagica), as well as for those by no means uncommon cases of acute poliomyelitis in which the virus has implicated brain as well as cord, and for which the expression polio-encephalo-myelitis has frequently been employed. In practically all widespread epidemics of poliomyelitis this variety is met with, as was fully discussed by the late Dr. F. E. BATTEN in his Lumleian Lectures of 1916, and has been mentioned by numerous other authorities. Even in the ordinary sporadic instances of the affection one occasionally encounters a case with cranial nerve or other encephalic involvement. It is not impossible that some of the rare cases of sudden death in children following an indefinite malaise are due to an unrecognised polio-encephalitis of the bulb—that is to say, a poliomyelitis whose incidence has been on medullary centres. The other acute infections of the nervous system that might be here mentioned include acute ascending meningo-myelitis, Landry's paralysis, and acute toxic polyneuritis. Round Landry's paralysis much controversy

has raged, nor can it be asserted that the problem is solved. That, clinically speaking, there is an acute ascending motor paralysis which implicates proximal rather than distal limb segments and which occurs with or apart from epidemics of poliomyelitis must be accepted; the difficulty is to determine its pathological specificity. The disease called acute ascending meningo-myelitis differs from Landry's paralysis in its involving the cord funiculi indiscriminately, hence the concomitance of sensory and sphincteric disorders; on occasion it spreads to the brain, even to the optic chiasma, so that the clinical picture of a medullary or pontine or mesencephalic polio-encephalitis may be produced. Possibly this rare affection is a sort of ascending spinal lymphangitis, but in any case differentiation from other acute spino-cerebral lesions is obviously not easy except in clearly cut instances. An acute toxic polyneuritis may readily implicate vital respiratory and circulatory neural mechanisms and prove rapidly fatal without revealing itself in the periphery of the limbs to any notable extent. Apart entirely from the conditions enumerated above, the neurologist sees cases of infantile cerebral hemiplegia or diplegia which, by exclusion of syphilitic and traumatic and other morbid processes, he sets down to a polio-encephalitis of unknown origin, a polio-encephalitis not to be facetiously interpreted as a mere variety of acute poliomyelitis, since the cases seem to make their appearance at any time of the year and without any seasonal incidence. As a general rule, the child becomes unwell, probably develops a few fits, unilateral or otherwise, and is then seen to be paralysed on one side.

Obviously, then, amid these cross-divisions the seeker for diagnostic exactitude and the nomenclature purist alike will find themselves beset with difficulties. The trouble has arisen largely through the continuance of a pathological term by usage when it no longer fulfils the postulates that precise terminology demands; Dr. POOLE's interesting cases, in fact, raise more than one problem of practical importance. It is regrettable that the exigencies of the occasion, their brief duration, and the uncertainty of their character or prognosis, naturally precluded that minute and searching neurological investigation which they deserved. The absence, too, of subsequent microscopical examination, or at least the fact that Dr. POOLE makes no allusion to this, renders speculation as to their ætiology and pathology more than a little futile. From the clinical description a diagnosis of acute polio-encephalitis seems justifiable; from the pathological, the data are incomplete. Were histological confirmation of an inflammatory encephalic process forthcoming, the exact diagnosis would still be wanting, for the simple reason that we cannot always, or often, determine the nature of the postulated virus by the type of tissue-reaction. A pathological classification is preferable to a clinical one, but the pathogenic is superior to both. Until we know the features, cultural and otherwise, of the virus which we presume underlies epidemic encephalitis and of those which we imagine, similarly, are responsible for the other types of encephalitic and polio-encephalitic cases mentioned above, we shall have as much difficulty in differentiating our clinical material as the internist formerly had with alimentary infections of a typhoid type. In respect of acute poliomyelitis a more advanced stage has been reached, ætiologically and bacteriologically, and the same is true of those cases we have called polio-encephalo-myelitis. The strains of the coccus of epidemic cerebro-spinal fever, similarly, are known and are recognisable; but when we come to polio-encephalitis pure and simple, we can get at

present no further. We are not inclined to class epidemic encephalitis, still less the rarer affections to which allusion has been made, as sub-varieties of an all-embracing influenza, and the question of a pleomorphic organism behind these varying manifestations of brain inflammation is not, we believe, anywhere within reach of a solution. In a recent communication Prof. A. J. HALL, of Sheffield, has argued for a synthetic as opposed to an analytic approach to the encephalitis problem; but a consideration of the vexed matters which we have been discussing will, we think, convince the physician that the work of analysis must be prosecuted further ere the synthetic stage can be entered on with advantage.

"ELECTRONIC REACTIONS."

At a joint meeting of the Sections of Medicine and Electro-Therapeutics of the Royal Society of Medicine on Friday last (Jan. 16th), Sir THOMAS HORDER, speaking on behalf of himself and his colleagues, Dr. C. B. HEALD, Colonel H. P. T. LEFROY, Mr. WHATELY SMITH, and Mr. M. D. HART, read an account of an investigation into the Abrams technique and the related procedures of Dr. W. E. BOYD, the general title of the paper being "Electronic Reactions." We publish elsewhere an account of the meeting. The decision of the Sections to give a hearing to the communication was taken, we understand, with some reluctance, inasmuch as the alleged discoveries of ABRAMS formed the avowed starting-point of the investigation, and these discoveries have appeared hitherto to the medical profession to present no points worthy of discussion, the claims of healing being unprecedented and uncontrolled, and the underlying physical manifestations being inexplicable upon scientific grounds. The communication read by Sir THOMAS HORDER, which may be regarded as a report from himself and his colleagues upon "Electronic Reactions," suggested that while the labours of ABRAMS were of no account, those of Dr. BOYD at Glasgow, which had their starting-point in ABRAMS'S work, presented features that it would be wrong not to discuss, in view of possible developments. In those circumstances it will no doubt have been a disappointment to those engaged in the new investigation that, when a meeting of two Sections of the Royal Society of Medicine had heard the report they decided not to allot a date for debate on the questions involved.

The question therefore arises whether more harm than good has been done by the reading of the report, versions of which have already made their appearance in the lay press, upon which reflections have been founded of a misleading character. The authors of the report find that "electronists" using the Abrams technique have exploited the public, but the public on reading the report, or summaries of it, may not recognise the distinctions between the Abrams technique and the Boyd technique as fundamental, and may consider that some new and mysterious agency, related to the researches of ABRAMS, has now been recognised as at any rate containing therapeutic virtues. It is true that the report contains the clearest possible statement that there is no justification whatever for applying the alleged discoveries to the diagnosis or the treatment of disease, but what is to make the public accept this statement? And what is to make certain practitioners feel that "Short is the friend not Codlin," and accept the implied condemnation of their present activities? The reply of Sir THOMAS HORDER and his colleagues here would be

(or might be) that their considered report on the whole subject ought to force "E.R.A." practitioners to submit their work and results to carefully controlled experiments, as Dr. BOYD has done with his work at Glasgow. But we doubt the falling out of this position, for those who do not desire any scrutiny of the sort may consider that they have been judged already, and now prefer to point for their answer to results which they are prepared to claim without further support.

Dr. BOYD has allowed Sir THOMAS HORDER'S committee every opportunity for making and controlling full inquiry, and in this they were assisted at one period by the research officer to the Society for Psychical Research, as representing the highest available authority on the subject of conscious or unconscious trickery. All the investigators seem to have been satisfied with the conditions, and to feel justified in stating that certain substances, when placed in proper relation to Boyd's "emanometer," produce changes in the abdominal wall of the subject of a kind which may be detected by percussion. They point to figures as showing that such detection must connote real differences upon percussion and cannot be dependent upon chance. Our opinion is that the researches ought not to have left the cradle of a physical laboratory. The work is not ready for clinical experiment, while to anything like open debate in medical circles, the want of common grounds of accepted medical knowledge, and even of a generally accepted nomenclature, appear as fatal drawbacks. The absence of any claim to therapeutic advancements in connexion with "electronic reactions" indicates that the alleged findings should be tested in physical laboratories.

ANTI-VENEREAL PROPAGANDA.

THE existence of two societies concerned with propaganda and educational effort directed to the diminution of venereal diseases has been evident for several years; and the clashing between these bodies and the competition between them for public favour have undoubtedly been inimical to the object which is common to both. The Trevethin Committee was appointed to consider the possibility of combined action, and in due course reported in terms with which both the National Council for Combating Venereal Diseases and the Society for Prevention of Venereal Disease expressed satisfaction. Thereafter a liaison committee representative of both societies was formed, and in the first instance agreed on a memorandum which embodied the chief educational objects of the two societies. From the viewpoint of the first-named society their representatives must have felt considerable difficulty in agreeing to its contents, though if these are taken in their context no serious objection need be raised. The signature of this memorandum was justified by the importance of securing the limitation of propaganda as to personal disinfection to selected persons, or to persons definitely asking for advice on disinfection; and by the association in all printed matter with this advice of moral counsel and warning as to the dangers of promiscuity, whether disinfection is employed or not. A subcommittee of the above-mentioned liaison committee was further instructed to explore the legal possibilities of amalgamation between the two societies; and after legal consultation we are informed that the difficulties in the way of this were found not to be serious. The scheme for amalgamation which was prepared has not, however, been discussed, as, on further consideration, the Society for Prevention of Venereal Disease, at a recent meeting

of their executive committee, decided that fusion between the two societies appeared impracticable in view of the constitution and incorporation of the National Council, and that in their view combined action by coöperation remains the most practical and advisable policy. This decision is regrettable; but in view of its decisive character it becomes necessary to fall back on such coöperative counsel between the two bodies as may be feasible. Were it practicable for Sir AUCKLAND GEDDES, the president of one, to consent to become the president of both societies, the prospect of such coöperation might be bright. In any case the liaison should remain.

Meanwhile, there necessarily will arise questions on which combined Parliamentary representations may be made, and others on which consultation will be desirable on points on which there is common agreement. The importance of the varied educational work of the National Council, which is rapidly increasing in scope, cannot be exaggerated. Nor can there be doubt as to the desirability of giving exact scientific advice as to disinfection to persons requiring it, and of enabling druggists to sell materials for this purpose, embodying the exact advice just indicated, along with warning against exposure to the need for using it. The exact limitations of such advice are not likely to be finally settled until or unless the Ministry of Health make a definite pronouncement on this subject. The position demands this, and we trust that it will soon be given. When these conditions are fulfilled, we may hope that less will be heard of ardent propagandism in any special limited direction; that the problem of prevention of venereal disease will be viewed as a whole; and that all branches of preventive work, including a larger share of general social educational work, will get attention.

ISO-PROPYL ALCOHOL AS A SUBSTITUTE FOR METHYLATED SPIRIT.

RECENT modifications in the composition of methylated spirits introduced by the Excise authorities are of far-reaching importance, and from the standpoint of the legitimate user of the spirit they can only be viewed as deplorable. The addition of a small quantity of dye-stuff a few years ago was a subject for regret to many, but the recent addition of pyridine to the denaturants used is a far more serious matter. Pyridine is sufficiently irritant to the skin to render the use of the spirit containing it unsuitable for the preparation of lotions, or for washing the skin prior to operations, or for use in a hypodermic syringe. Industrial methylated spirit may be free from these drawbacks, but the restrictions surrounding its employment place it outside the reach of the practitioner. It seems almost impossible to suggest a denaturant which could be added to the spirit which would satisfy both the demands of the revenue authorities and the requirements of the legitimate user. The most important of these latter requirements is, of course, freedom from irritant or toxic action, while miscibility with water is also a most desirable characteristic. At the present time the best way out of the difficulty appears to be found in the use of iso-propyl alcohol. This substance, which can be manufactured by the reduction of acetone, resembles ordinary ethyl alcohol very closely in its properties, being almost identical in boiling-point, density, odour, and miscibility in water, and having very similar solvent properties. In these respects it is more akin to ethyl alcohol than to its own isomer, normal-propyl alcohol. Furthermore, it appears to be free from toxic and irritant action, and is quite suitable for all purposes for which the old methylated spirit or the modern industrial spirit could be used. Indeed, its toxicity is probably a great deal less than

that of methylated spirit.¹ The technical product contains about 95 per cent. of the alcohol and is available under various names, such as "avantine." The only real drawback seems to be that of price—namely, about 40s. to 45s. per gallon; but this is, of course, considerably less than that of rectified spirit, duty paid. Iso-propyl alcohol is also made in America from natural gas, but there do not seem to be any available data as to the physiological purity of the alcohol from this source.

Annotations.

"Ne quid nimis."

CORRECT POSTURE.

POSTURE is defined as the relative disposition of the various parts of anything and in a special sense as the position and carriage of the limbs and the body as a whole. In a more limited sense the word is used by Mr. Muirhead Little, in his article (see p. 197) on the Treatment of Postural Defects in Children and Adolescents, to mean the habitual attitude of the body and limbs when not in movement and especially in the upright position of the trunk. Postural defects are such faults of attitude as are not connected with permanent structural deformity and, in general, can be corrected by the patient's volition or by the application of small outside forces. As in the erect position posture must be affected by the position and form of the supporting lower limbs, it becomes necessary to take into consideration the condition of the feet and legs, seeing that equilibrium is only possible when a vertical straight line passing through the centre of gravity falls inside the boundaries of the supporting base. According to experiments made by Reynolds and Lovett,² this line falls normally just in front of the ankle-joint and the knee-joints, in front of most of the vertebral joints, and probably also in front of the hip-joints, although these latter are so situated that this position is only inferred from experiments made upon the dead body. This disposition of the joints as regards the centre of gravity enables the erect position to be maintained with a minimum of muscular action, owing to the existence of strong ligaments upon which much of the strain is thrown. To the question as to what is the normal erect posture there is no definite answer, for while all observers will agree that certain postures are abnormal, few will agree as to the exact degree of curvature in the several regions of the spinal column which constitutes abnormality. It is well known to sculptors and students of ancient art that the male Greek figure, as represented in such statues and reliefs as have come down to us, differs considerably from the best models of modern times. The difference would seem to consist chiefly of a greater sharpness of the lumbo-sacral angle. The tracings reproduced from photographs of statues and casts in the British Museum in Mr. Muirhead Little's article show this peculiarity, which seems to manifest itself in male figures only. We have no means of knowing whether these sculptures were true to nature or not, but at least they show that the ideal of manly beauty in the time of Pheidias differed from that of the orthopaedic surgeon of to-day. In the United States attempts have been made to establish a normal standard by the examination of a number of healthy young men at the beginning of their university course. Dr. Lloyd T. Brown,³ of Boston, has published the results of an examination of 746 freshmen at Harvard

¹ Martindale and Westcott: *Extra Pharmacopoeia*, eighteenth edition, p. 131.

and Dr. Robert Cook¹ those of 1393 at Yale University, but without establishing a really definite standard. Lloyd Brown, however, divided his cases into four grades, A, B, C, and D. Only about 7 per cent. of his cases were found worthy of Grade A. Figs. 5 and 6 (see p. 198) show this type standing at attention without conscious effort (5) and when he has been asked to correct his posture (6). In a later paper by Lloyd Brown and Roger I. Lee, dealing still with Harvard freshmen, rather different outlines are given as typical of the four grades, thus showing that the standard of normality is not yet quite established. It was found that in the highest grade a straight line drawn from the tip of the external malleolus to the middle of the great trochanter, if continued upwards, would pass through the shoulder (head of the humerus?) and the front of the external ear.

THE GREAT PLAGUE.

"What eye would not weep to see so many habitations uninhabited, the poor sick not visited, the hungry not fed, the grave not satisfied? Death stares us continually in the face in every infected person that passes by us, in every coffin which is daily and hourly carried along our streets."

SUCH was the impression made by the Great Plague upon an official of St. Paul's Cathedral, by name John Tillison, and chronicled by him in a letter to Dean Sancroft. Many books have been written about the plague of 1665, some from the medical side, as, for instance, "Loimographia," by William Boghurst (an admirable edition of which was edited by the late Dr. J. F. Payne for the Epidemiological Society), "Loimologia," by Dr. Nathaniel Hodges, and "Loimotomia" by Dr. George Thomson, who has left us the sole record of a post-mortem examination upon a plague patient. In fiction there is, of course, Defoe's "Journal of the Plague Year" and Ainsworth's "Old St. Paul's." But for a carefully documented and vividly written historical account of the plague we must allow that Mr. Bell's recent book² is the best that we have seen, taken as a whole, and is a fitting companion for his other book the "Great Fire of London." Mr. Bell apologises in his preface for the quantity of references with which he says his pages are peppered. For our part we consider that no apology is needed and we only wish that more writers would give their references as carefully. Mr. Bell has an extraordinary flair for picking out illuminating passages from the writings of his authorities. Quite early in the book (p. 59) we find the following remark in a letter from Sir Robert Long, auditor of the Exchequer, to his clerk:—

"I pray you use all possible care to preserve yourselves and my house. . . . Lett not the porter come into the house; take all course you can agaynst the ratts, and take care of the cattis; the little ones that will not stirre out may be kept, the great ones must be killed or sent away."

Long evidently had some idea that "the ratts" were a source of danger, and it is curious that he should not have seen that his cats might have been valuable assistants, even though, as is possible, they might have conveyed infection. The two regions of London where the plague was at its worst were St. Giles in the Field and the other parish of St. Giles—namely, Cripplegate—both being poor quarters. Cripplegate lay in a waterlogged situation, where shallow ditches were clogged with filth, and in addition the great laystall in Moorfields, where all the rotting garbage from the streets was raked together, formed an ideal attraction for rats. Against this laystall the College of Physicians had protested in 1636, but nothing was done. Plague having obtained foothold, its spread was rendered easier by the mistaken policy of shutting up houses with all their inmates directly one case of plague occurred therein, a policy which, it is sad to say, was endorsed by the

College of Physicians. As in all epidemics, there were instances of both cowardice and heroism on the part of the clergy and the medical profession, and Mr. Bell gives many details in pp. 223–226 and p. 290 respectively. A horror lay over the city, and as in Egypt of old there was scarce a house where there was not one dead. Mr. Bell is rightly severe upon the Court, which retired to Oxford, leaving Albemarle to do his best for stricken London, together with Lawrence, the Lord Mayor; and admirably they did their work. He also gives with hardly-veiled satire Evelyn's description of the Fellows of the Royal Society meeting at the Durdans, where he found Dr. Wilkins, Sir William Petty, and Mr. Hooke contriving chariots and other mechanical inventions. In one respect Mr. Bell has departed from his eminently "indifferent" treatment of his subject, for he goes out of his way to lament the sufferings of the Non-conformist ministers who were ejected on St. Bartholomew's Day, 1662. It is a matter which has but little to do with the Plague, and granted that the ejected ministers had grievances, it must also be remembered that most of them had been intruded into the livings when the rightful holders had been turned out by Parliament in 1640 and later. Granted, too, that the Conventicle Act and the Five Mile Act were oppressive, as they undoubtedly were, the latter was only an extension of an ordinance of Parliament dated August 19th, 1643, whereby one-fifth of the profits of their livings might be granted by sequestrating committees to the turned-out clergy, but on condition amongst others that they must remove out of the parish. Mr. Bell has, we see, read Calamy's book on "Non-Conformity," and we imagine that so learned a man as he must have read Walker's "Sufferings of the Clergy." The 2000 ministers who were ejected at Black Bartholomew-tide were not all learned and saintly men, though it is true that some were really sufferers for conscience' sake. But many were not in Holy Orders, and others we find from Calamy were illiterate. Thus, on p. 731 of Volume II. of the 1713 edition of Calamy, we find Mr. Ellis, a skinner from London, Mr. Miller, a London bookseller, Mr. Miles and Mr. Froude, both Anabaptists; on the next page Mr. Jones, an honest plowman, Mr. Jenkyn Jones, a Catabaptist, Mr. Joseph, who "spoil an ingenious husbandman to become an Ignorant Preacher," and lastly Mr. Thomas, who "turn'd a drunken steward." But when Mr. Bell is writing of the Plague and its attendant horrors he is admirable.

THE SUPERIORITY OF THE NON-SMOKER.

Dr. Rosslyn Earp's statistical inquiry at Antioch College, Ohio (U.S.A.), which we publish on p. 213, shows that while the non-smoking students of the College do not come out better than the smoking students in the ordinary cardio-vascular tests, yet in practice the non-smokers are the better athletes and show a better record of scholarship. We agree with him that the size of the population examined justifies the conclusions drawn, but it will certainly be urged that the population, as selected, may have bias apart from the tobacco habit. Athletes, as a group, do not smoke during training, and before any contest all the best athletes are known to be in the non-smoking group, with the result that that group would win the athletic events. Moreover, experience among school-children suggests that good physical and good mental equipment go together, so that, having placed non-smoking athletes in a group, it is natural to find in that group the better mentalities. Nevertheless, Dr. Earp's grading of Table C is good enough to suggest that tobacco may have some influence per se. A year or two ago an attempt was made on a small scale¹ to compare the mental work of smoking and non-smoking telegraph operators, using output as the criterion. The numbers at risk were few—viz., seven heavy smokers, five light smokers; the heavy smokers did not do so well as the light.

¹ Robert J. Cook: Report of the Orthopaedic Examination of 1393 Freshmen at Yale University, Jour. Bone and Joint Surgery (Boston, Mass., U.S.A.), 1922, iv., 247.

² The Great Plague in London in 1665. By Walter George Bell, F.S.A. London: John Lane. 1924. Pp. 374. 25s.

¹ Journal of Industrial Hygiene, October, 1920.

Output, again, was the measure in an investigation¹ of a larger group of glass bottle makers in relation to the physical effect of smoking. Smoking had little effect, nothing statistically reliable, but chewing markedly lowered output. There was no cross-influence of athletic training to invalidate the grouping in these inquiries. Examination of Dr. Earp's Table A does not show the regular progression on any observation made, upwards or downwards, moving with the amount of tobacco used, which would be desirable to bring conviction. The heavy-smoker group, in fact, gives results which tend to be closer to the non-smokers than to the moderate or slight. These results do not agree with either athletic prowess or mental capacity, and suggest that in this case pure tests are not being applied. The inquiry, however, is well worth making and the material for it is abundant.

FOOD PRESERVATION BY COLD.

THE dependence of this country upon imported food, much of it perishable food, makes a scientific study of the principles involved in the action of cold upon foods of great practical importance. The Report of the Food Investigation Board² for 1923, recently issued, contains, amongst numerous other matters of importance, an account of various studies dealing with this subject.

As regards frozen meat, there are well-recognised defects which detract from the practical utility of freezing and make it inferior to chilling. Actual freezing is, however, necessary for long-distance travel. The essential disadvantage of freezing meat is in the loss of texture when thawed, causing physical alterations and a tendency to drip. The latter is due to a separation of the water previously held within the fibres, which drains away from the cut surfaces, carrying with it some of the nutritive properties of the meat. It has been shown by earlier investigators that this undesirable change can be prevented if the rate of cooling is sufficiently rapid. Such a rapid cooling of beef is not practicable, since no known methods are adequate to achieve it in masses so large as a quarter of beef. To remove the drawbacks of freezing beef it is therefore necessary to try and discover some other method of producing the same effect which would not demand so high a rate of cooling. The best line of attack is to study the scientific principles concerned in the freezing of foods, and these were studied experimentally along a number of different lines.

Eggs were selected as a useful food to study, since previous work had shown that with them factors (such as limiting temperatures) other than the rate of cooling also affect recovery without physical damage. It was found during the year that the yolk may be preserved without sensible change in two ways—either by never allowing the temperature to fall below -6°C ., or by freezing and thawing with great rapidity. It is probable that some irreversible change of the nature of a coagulation occurs at temperatures between -6°C . and some unknown lower limit, but does not occur if this critical interval is hurried over with sufficient rapidity. Further light upon the problem was obtained by a study of the changes in a simple colloid system, that adopted being a mixture of gelatin and water. Where such a jelly is frozen and thawed water drips away freely—i.e., there is a definite separation of the water from the gelatin. These problems are still being studied, one interesting line of inquiry being measurements of the rate of advance of a fragment of ice in a cylinder of overcooled (-3°C .) jelly. The rate was found to be constant through the length of the tube, but the rate of advance was influenced by various factors, including the percentage of gelatin. Other studies have been carried out in regard to the autolytic changes in cod under frozen conditions. Foster and Fearon in 1922 found that the autolysis of beef or mutton frozen

rapidly in cold brine or mercury was similar to that of fresh unfrozen beef or mutton, whereas if the flesh had been frozen rapidly in air the course of chemical change was strikingly different. These results were confirmed for the cod, and the cause of the difference found to be due to the separation, in muscles which had been slowly frozen, of fluid containing proteins, ferments, and other organic substances in solution. It is this liquid which drips away from the flesh on thawing, and it is in this fluid that the more rapid autolysis takes place. The preservative action on fish of ice containing small quantities of antiseptic was tried, but on the whole the results were not satisfactory, because the flesh became impregnated with the antiseptic.

Another section of the report gives interesting particulars of results obtained by cold in the storage of different fruits. To obtain comparative results it is necessary to have some means of determining the commercial storage life of the fruit. Most of the work was done with apples, and for this and other fruits an arbitrary point for the end of commercial storage life was fixed as the length of time the fruit can be stored before loss due to fungal rots or functional diseases amounts to 10 per cent. In general, the results of work extending over three seasons was a pronounced extension of the commercial storage life of the apple by the action of cold storage due to a retardation and alteration of the natural ripening processes and to the delay or inhibition of fungal attack. In exceptional cases these satisfactory results were not obtained and ordinary storage yielded better results; the causes of this were studied and determined. Experiments with plums were less complete, and have yet to be placed upon a systematic footing. From cold storage trials with strawberries kept at 1°C . favourable results were obtained, and in this way they were kept in good marketing condition for seven and, in some cases, for ten days. When marketed the fruit realised the same prices as fruit freshly gathered. With such a rapidly perishable fruit as strawberries, the practical utility of this work is obvious.

TREATMENT OF MALARIA WITH PERACRINA.

AN account¹ of his experiences of the treatment of malaria in the famine districts of the Volga with the new drug "peracrina" has been given by Dr. J. Walker, who is the chief of the Swiss Red Cross Hospital in Russia. Peracrina is manufactured in Berne by the Haco Company in the form of sugar-coated pills, and is a combination of an albuminous substance with tryptaflavine. Each pill of 0.5 g. contains one-tenth of tryptaflavine. The effects of the absorption of this ingredient become apparent after ingestion of 3 g., the stools becoming coloured yellow and the urine fluorescent. As the result of his experiences in Russia, Dr. Walker believes that peracrina has a distinct and beneficial action on malaria, but that tryptaflavine alone, without the albuminous adjunct, is inactive. The series comprised 116 cases, of which 73 were benign tertian, 26 subtertian, and 22 mixed infections. Of these only 25 proved to be resistant to the drug, and the author is therefore hopeful that in peracrina we possess a specific for malaria which may possibly even replace quinine in the treatment of this fever. Further experiments are now being prosecuted in Syria and amongst the refugees in Greece. The dosage is as follows: For children of 3-6 years of age, 4-6 pills representing 2-3 g. of peracrina; from 6-8 years, 6-9 pills (3-4.5 g. peracrina); from 9-16 years, 8-12 pills (4-6 g. peracrina); adults 12-18 pills (6-9 g. peracrina). The course of treatment was extended in some cases over six weeks. A preparation, known as "peracrina 404," and possessing a high iodine-content, was not so active against malaria, and in two cases which proved fatal seemed to give rise to iodine poisoning. It was difficult to follow up the cases, but according to a recent report, out of

¹ Ibid., May, 1921.

² Annual Report for 1923. H.M. Stationery Office. 3s.

¹ Walker, J. (1924): Archiv für Schiffs- u. Tropen-Hyg. vol. xxviii., pp. 540-570.

30-40 patients who had been traced, only two had suffered from a relapse. The discovery of a specific more active than quinine, and shorn of its many disadvantages, would be eagerly welcomed by the profession, but more exact observations controlled by periodic blood examinations are necessary before optimism is justified. A perusal of the temperature charts and protocols in Dr. Walker's paper is not very convincing; we note in several cases the simultaneous exhibition of quinine hydrochloride had to be resorted to before resolution of the fever took place.

PRISONS.

THE report of the Commissioners of Prisons and the directors of convict prisons for the year 1923-24 has recently been issued.¹ It shows that notwithstanding the tendency for an increase in prison population to occur during the years following a war, and the large numbers of unemployed, the total receptions into the prisons of this country have again decreased in number. This in itself is a satisfactory feature of the report, and not less so is the account of the great amelioration of prison conditions which is gradually taking place. Educational facilities, particularly for adults, continue to make progress; there exists now in several of the prisons "clubs" or "honour parties" who hold meetings at which games are played and debates take place, and lectures, concerts of good music, &c., continue to play a part in the routine of the modern prison. The work at the Borstal institutions shows further improvement; at each of the three main boys' institutions—Borstal, Feltham, and Portland—there are now four houses each in charge of a housemaster, and the influence of a matron also helps the boys in the direction of their lives towards useful citizenship. It is interesting to learn that the officers of these institutions are now wearing plain clothes and the discarding of uniforms has had no untoward effect on the discipline. Although, as the report points out, this may seem a small matter in its beginnings, it is "one which may go far to promote the real spirit of a training school." A committee has been set up to consider the question of diet. The medical commissioner, Dr. G. B. Griffiths, also calls attention to the conservative treatment of prisoners' teeth. He suggests that long term prisoners would greatly benefit in health and well-being if an inspection and necessary fillings were carried out at the beginning of a sentence. The high state of general sanitation of the prisons is indicated by the small number of cases of infectious diseases notified during the year; four cases were reported from the local prisons and two from Borstal institutions. So far, then, the report seems fairly optimistic in tone, but there is another side to the picture. Special attention is drawn by the governors of two of the prisons to the increasing number of youths who, unable to find employment on leaving school, have their characters undermined by several years of idleness and drift into crime. This class of criminal, as the medical officer of the Feltham institution points out, is mainly derived from those children who during the war were deprived of the control and guidance of their fathers and were often allowed to run wild with plenty of pocket money; here the absence of male teachers from the schools led to further relaxation of discipline. There is a strong plea from the medical officer of the Birmingham prison for more satisfactory treatment of these young delinquents. Their "criminal" conduct is, he says, only one aspect of abnormal conduct which often has its roots far back in the early years of life. He suggests that abnormal conduct should be looked at as a whole and that the various authorities, those dealing with education, those concerned with the care of lunatics, mental defectives and epileptics, and those working particularly with criminals should co-ordinate their activities against all forms of "anti-social" conduct. This suggestion

seems a sound one and it merits close attention. We quote one sentence from the report in the hope that it will encourage those who give of their scanty leisure to the promotion of social welfare. It is stated to be "rare for a lad or girl to be received into prison who has been a member of a good boys' or girls' club, a boy scout or a girl guide, or a member of the Church Lads' Brigade."

DR. F. J. ALLAN'S RETIREMENT.

AT the beginning of this year Dr. Francis J. Allan retired from the position of medical officer of health for the City of Westminster, and his retirement means the loss of a very able and far-seeing member of the public health service. Dr. Allan acted as assistant to the late Sir Henry Littlejohn, and was some years in practice as a general practitioner before he was appointed medical officer of health for Shoreditch in 1890. Two years later he transferred to the Strand, and when on the creation of the metropolitan boroughs Westminster came into being by the amalgamation of the Strand District, St. George's, Hanover-square, St. James's, St. Martin's, St. Margaret's, and St. John's, Dr. Allan was elected medical officer of the newly formed borough. In 1892 he was appointed lecturer in sanitary science at King's College, and since 1915 he has been lecturer in public health in the Westminster Hospital Medical School. He is one of the trustees of the Society of Medical Officers of Health, of which he has been president, secretary, and editor of *Public Health*, the official journal of the Society. During the war Dr. Allan rendered great assistance to the metropolis as a sanitary expert, and he had the supervision of large numbers of refugees. In recognition of the latter services he was awarded the Albert Medal by the King of the Belgians. Dr. Allan's services to the City of Westminster have been more than merely administrative, and the influence of his work has had far-reaching results. It was through his representations under the Housing Act that the large and formerly unsavoury area (Clare Market) between the Strand and Holborn was condemned and cleared, leading to the formation of the present beautiful avenue of Kingsway. He was also instrumental in forming the first health society in Westminster, which eventually became the model on which other health societies have been formed throughout the country, and which may well be claimed as the foundation of the maternity and child welfare schemes now universally adopted. We are glad to know that Dr. Allan is still retaining his connexion with the Westminster Health Society and other bodies in Westminster, as well as his lectureship in the Westminster Hospital Medical School. The Westminster City Council have placed on record their high appreciation of Dr. Allan's services. It is to his personality that the smooth working of his department has been to no small extent due.

CLASSIFICATION OF MENTAL DISORDERS.

THE Special Committee of the British Medical Association which drew up the Memorandum of evidence to be set before the Royal Commission on Lunacy fully recognised the difficulty of dealing with mental disorders owing to the great variety of conditions presented. Thus the most lasting and grave forms of mental unsoundness may, at their onset, present only a mild type of mental disturbance. On the other hand, some of the most acute forms may be of only temporary duration, almost sure to recover, and possibly unlikely to recur. Then, again, some of the forms are marked by a natural tendency to remission and recurrence with intervals of apparent mental health; others, and these perhaps the most dangerous forms of mental disorder, are very difficult to detect and are carefully concealed by the patient for long periods. There are also chronic forms which

¹ Annual Report of the Prison Commissioners, 1923-24. London: H.M. Stationery Office. Pp. 90. 1s. 6d.

present no dangerous or conspicuously objectionable characters. If the best possible is to be done for the patient as a sick person the facilities for treatment and the types of accommodation must be sufficiently various to suit all these wide differing conditions. The Committee therefore drew up a scheme for the classification of patients suffering from mental disorders, which appears as an appendix to the Memorandum and is here reproduced. The scheme is based chiefly on the well-being of the patient combined with proper care for the safety of the community.

Scheme for Classification of Patients Suffering from Mental Disorders.

On a later page we print a general summary of the Memorandum and of the evidence given by representatives of the Association before the Royal Commission.

THE CORRECTION OF ASTIGMATISM.

FOR more than sixty years the prescribers of spectacles have been content with finding the cylindrical lens that will correct the corneal astigmatism for distant vision, and they have then assumed that the same cylinder will correct this astigmatism when used for near work. In the current number of the *British Journal of Ophthalmology* Mr. A. S. Percival has shown that this is not the case. The mathematic form of the article will not appeal to the ordinary reader, but the gist of the conclusions is this. If no presbyopic addition be given for close work, the power of the cylinder when used for near work must be increased by about 9 per cent. If a ± 5 D. cylinder corrects the corneal astigmatism for distance, it will require a ± 5.45 D. cylinder to correct this astigmatism for close work. If a full presbyopic correction of $+ 3$ D. sphere be given for reading, no alteration need be made in the cylinder; if a smaller correction, say $+ 2$ D. or $+ 1$ D., an addition of 6 or 3 per cent. respectively will be necessary if the cylinder be of high power. The practical application of Mr. Percival's observation is clear. For weak cylinders the amount to be added is negligible: for instance, a 1 D. cylinder for distance should only become 1.09 for reading. But where high-powered cylinders are required, better visual results for reading are obtained by an appropriate increase in the power of the cylinder.

THE anniversary dinner of the Medical Society of London will be held at the Grand Hotel, on Wednesday, March 11th, at 7.30 P.M.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CVI.

THE TREATMENT OF POSTURAL DEFECTS IN CHILDREN AND ADOLESCENTS.

THE spinal column consists of four regions, which are alternately rigid and flexible. From below upwards there are: 1. The rigid sacrum. 2. The flexible lumbar region (including the lowest two thoracic vertebrae) capable of bending in all horizontal directions and of a considerable degree of rotation. 3. The thoracic region, including only the second to the tenth thoracic vertebrae. No appreciable movement is normally possible in this region, although the normal curve may gradually be altered from various causes. 4. The mobile cervical region (including the first thoracic vertebra), in which bending in all directions and some rotation is possible. The regions most concerned in the posture of the body are the lumbar and thoracic, each of which reacts on the other, because to attain or preserve equilibrium an increase of curvature in one region must be compensated by an increase of curvature in the other. The lumbar curve is also affected by the position of the head. An increased lumbar curvature may also be compensated by an inclination of the trunk forwards pivoting on the hip-joints. While the limits of the range of motion are set by the shape of the articular surfaces and the length of the ligaments, the position assumed within those limits depends on muscular action, which is capable in the course of time of enlarging the range of motion in one or another direction. A similar but more objectionable result may be attained by the action of gravity, if unregulated by muscular action.

From what has been said as to complementary curves, and as to the rigidity of the curve in the thoracic region, it would be expected that extensive changes of the figure could only be brought about by long-continued, slowly acting agencies. Actual experience accords with this expectation. The relative strength and tonicity of the muscles constitute the immediate cause of the attitude assumed in the standing-still position. Figs. 1 to 4 represent the grades A, B, C, D, into which R. I. Lee and Lloyd T. Brown¹ divided the Harvard freshmen examined by them in the attempt to establish a normal standard. If the abdominal muscles are over-balanced by the lumbar muscles, an exaggeration of the lumbar curve results. Over-action or contracture of the psoas muscles leads to a like effect. Such relative weakness of the abdominal muscles may be the result of over-stretching by distension of the belly. Muscular fatigue is a common cause of postural defect. Most of us are aware that when we are tired there is a tendency to relax the muscles, and to allow the spine to collapse, throwing all or most of the strain on the ligaments, whereas when we are fresh and vigorous we sit or stand without conscious effort with the trunk and neck well braced up. Incidentally, the degree of curvature in the several regions of the body which constitutes abnormality is not an easy matter to determine, and even the normal posture regarded as ideal varies in different ages (see Figs. 7, 8, 9, 10).

Postural lateral deviation of the spine may be due to inequality of length of limbs or to a habit of standing on one leg in the stand-at-ease position. It disappears in the one case when the shortness of the limb is compensated by means of a high boot, or when in the other case the patient stands evenly on both, equally extended, legs. If it does not then so disappear, the deformity, although postural in origin, has gone

¹ Roger I. Lee and Lloyd Brown: *Journ. of Bone and Joint Surgery*, 1923, v., 753.

further and become fixed. There are also cases in which postural lateral deviation is due to want of tonicity in the muscles allowing the spine to sag to one side, just as it more often does in the direction of the normal spinal curves. Round shoulders, when not due wholly to abnormal curvature of the thoracic region of the spine, represent the direct result of relaxation, weakness, or atony of the scapulo-spinal

and hip flexion. A similar condition of the anterior muscles of the ankle favours excessive plantar flexion, to compensate which the knee and hip are hyper-extended. High heels are accused of causing defects of posture, as well as deformities of the toes. It is open to question whether this accusation is justified. As long as the heels are not so high as to place the foot in a position of such extreme equinus that no further plantar flexion is possible, it is difficult to understand how they can affect the posture of the body.

Inequalities in the length of the lower limbs must be compensated, knock-knee and coxa vara if found must be dealt with, as well as all other remediable abnormalities. The next step is to ascertain what is the best position which the patient can assume voluntarily and to train him so that he may know when he is in that position. For this purpose a large mirror is of considerable value. The patient being placed in front of it in his best position is able to see for himself what it is that he has to do. This is the more desirable because it is not unusual for a patient to put himself in a worse instead of a better posture when first told to hold himself upright.

Fig. 6 shows the effect of a well-directed conscious effort of correction from the position at ease in Fig. 5. When such a position can be maintained indefinitely *without* conscious effort a good deal of progress has been

made. Treatment includes every measure that tends to the improvement of health and strength, and excludes all those of a contrary tendency. It is in the stationary erect position that it is most difficult to avoid falling into bad attitudes and lolling, and

Figs. 1 to 4 (from R. I. Lee and L. T. Brown, loc. cit., 1923) represent the four grades A, B, C, D, among Harvard freshmen of the thin type. Figs. 5 and 6 (from L. T. Brown: Amer. Jour. of Orthop. Surg., 1917, xv., 774), represent a freshman of grade A, of heavy type, standing at his ease (5) and again when told to hold himself up (6).

muscles—that is to say, loss of the normal balance between them and the powerful pectoral group, from whatever cause arising.

Postural defects are generally the result of abnormal conditions and not the cause of them, but it must be admitted that if they are allowed to persist they probably aggravate those conditions, and thus a vicious circle is entered upon. The muscular weakness and atony which allow round shoulders and hollow loins and visceroptosis are themselves signs of malnutrition and faulty innervation, and the hygienic treatment which relieves the latter conditions will indirectly correct the postural defects. There is no lightning cure, but the example of army training which can turn the slouching recruit into an upstanding, well-set-up man, shows what may be done by unrelenting, well-directed treatment. Good results are only obtainable by oft-repeated and persevering efforts. Flat everted feet must be treated by exercises and the use of proper shoes and boots. Painful affections of the feet may prevent the normal distribution of weight by causing the patient to spare one part of the foot or feet, and to load unduly another part, either of conscious choice or instinctively. Thus, it is a common complaint by the parents of flat-footed children, that they are pigeon-toed, and they are brought to the surgeon because they turn their feet in. In such cases the weak inner side of the foot is unconsciously relieved and its flatness corrected by inversion and concomitant supination of the foot at the medio-tarsal joints. Inequality of length or contraction of any of the joints of the lower limbs may affect the general posture of the body by making it impossible for those limbs to support the centre of gravity of a normally poised trunk and thus necessitating an abnormal poise. Loss of normal muscle-balance acts in a similar manner. For instance, palsy or weakness of the calf muscles is followed by excessive dorsiflexion of the foot and secondary knee

Fig. 7. From No. 1655. Third Græco-Roman Saloon, British Museum. "Satyr dancing. Known as the Rondinini Fawn." Fig. 8. From No. 120 in the Cast Gallery, British Museum. "A copy of a statue by Polycleites, 2nd half of V. Centy. B.C." Figs. 9 and 10. From a Votive Relief, No. 2155. "Offering a torch to Artemis Bendis. About 350 B.C." The above show the Greek ideal of the great period. There is in these a comparatively sharp angle in place of the longer lumbar curve in Figs. 1 to 6.

therefore standing still should be as far as possible avoided, at any rate, in the early stages of treatment. When the patient is not actively occupied he should be seated or recumbent. In this connexion I am of opinion that cricket, which involves, for a large proportion of the players, much standing about doing

nothing, is not a suitable pastime for the subject of postural defect.

The Form and Dimensions of Chairs.

The form and dimensions of chairs are of great importance. Much has been written on school chairs and desks, and many patterns have been recommended, especially in the United States. The desiderata in a chair for reading differ much from those in a chair for desk-writing. The first should have a low seat of such a height that when the feet rest on the floor, its front edge does not press unduly on the posterior surfaces of the thighs. The seat should have a backward slope downwards of ten degrees with the horizontal. The back should be high enough to reach to the sitter's occiput, and should be set at an angle of at least 95 degrees with the seat, and thus at one of 105 degrees with the horizontal. In such a chair the whole of the back is supported and the slope is great enough to check any tendency of the spine to sag, especially if a small thin cushion is fixed to correspond to the lumbar region. For writing or for reading books which are too heavy to be held long in the hands, a sloping desk is desirable, which should be of such a height that its front edge should be at the level of the middle of the patient's sternum

when he or she sits upright. A sloping seat is of no advantage for use at a desk, but rather the contrary, and as the back of the chair does not come into use in desk-writing any chair with a level seat of a height as above described will be suitable.

Exercises and Massage.

To describe in any detail the exercises by which it is hoped to correct postural defects is beyond the scope of a short article such as this. They may be learned from a manual of physiotherapeutics, such as "Exercise in Education and Medicine," by Dr. R. Tait Mackenzie,² and are to be carried out by those trained in that branch. Suffice it to state that massage of relaxed and overstrained and undertoned muscles is of value, in addition to volitional exercises selected to enable the patient to attain and to maintain a normal healthy posture. In every scheme of corrective training the importance of the abdominal muscles must be borne constantly in mind.

ALASTRIM AND VARIOLA.

THE EXPERIMENTAL SIDE OF THE QUESTION.

BY J. C. G. LEDINGHAM, C.M.G., D.Sc.,
M.B. ABERD., F.R.C.P. LOND., F.R.S.,

CHIEF BACTERIOLOGIST TO THE LISTER INSTITUTE; PROFESSOR OF
BACTERIOLOGY, UNIVERSITY OF LONDON.

RECENT suggestions to notify as para-smallpox (or some such designation) the mild form of variola now current in this country have been criticised on the ground that, apart from the lack of "toxicity" and death-dealing power which constitute the chief features of the mild form, its clinical manifestations are indistinguishable from those of the old-fashioned variola. The further point has been raised that until clinical or bacteriological differences are formulated and proved, notification under a special term has nothing to recommend it. Prof. R. Jorge's¹ very able and critical survey of the whole question of alastrim *et hoc genus omne* deals perhaps rather summarily with the experimental and immunological side of the subject, his opinion being that while alastrim satisfies, in the main, the principles of Jennerian vaccination as evidenced by the protection of the vaccinated and the reciprocal immunity of the convalescents to vaccinia, it is not entirely justifiable to use vaccinia as a sort of experimental touchstone or substitute for variola. He does not appear, however, to be a dualist in the old sense. He would wish to be assured in the first place that alastrim virus can, like variola, be reduced to the condition of variola vaccine by passage through the calf, but, even if this proved to be possible, he would still hold that clinical and epidemiological features constituted a real difference. The results of the animal experiments quoted by Prof. Jorge seem to him confused and conflicting and consequently of little evidential value, but, on the other hand, it is clear that he has not adequately surveyed and appreciated the available data relating to this aspect of the subject. I propose, therefore, by invitation of the Editor of this journal, to detail somewhat more fully than Prof. Jorge has done the results of animal experiments which to my mind clearly establish the essential identity of alastrim and variola so far as that is possible in default of the fuller and more precise immunological data which only the artificial culture of these viruses will provide.

¹ THE LANCET, 1924, II., 1317, 1366.

The use of vaccinia as a touchstone in human and animal experiments has long been regarded as entirely valid in view of the now numerous demonstrations of successful variolisation of the calf whether by direct passage, oft repeated, or more frequently through the intermediary of the monkey. Moreover, the initial source of the current vaccine lymph of commerce, though often wrapt in obscurity, is almost certainly in all cases human variola.

Experiments on Man.

These concern the results of vaccination of recovered cases of alastrim, it being generally admitted by most of those who have recorded their experiences in various countries that as a preventive of alastrim recent successful vaccination is notoriously effective. I ignore for the moment certain experiences which seem to show that when alastrim does attack the recently vaccinated, its manifestations may be fully as florid as in the unvaccinated. Such happenings, in my opinion, simply serve to illustrate flaws in the immunising mechanism which declare themselves in all experimental work and which are most likely the immediate consequence of an insufficiently developed complement of viricidal body to meet a fresh virus attack. In this connexion also it should be borne in mind that the path of vaccination with its limited local range is not the path by which in all probability the full-blooded virus enters the system.

With regard to the reciprocal experiments, the following data may be adduced: Dickson and Lassale (1903), who investigated the "varioid varicella" of Trinidad, record that of 185 recovered cases 15 were successfully vaccinated, while de Korté (1904), in connexion with the South African amaas, reports that 14 cases vaccinated after recovery reacted "in varying degrees like individuals more or less protected by previous vaccination." Data concerned with the Brazilian alastrim are reported by Ribas (1910) and Rudolph (1911). The former found that the vaccination of 15 alastrim cases at periods of six months or later after recovery yielded positive takes in seven, while the latter vaccinated 20 recovered cases within one to six months with negative results in all. In a series vaccinated somewhat later, however, at 8-11 months, 3 out of 11 gave positive takes. Both Brazilian authors, impressed by these results, inferred that the immunity to vaccinia as conferred by alastrim was of relatively short duration. Robertson (1913), reviewing the outbreak of mild small-pox in New South Wales, states that the performance of vaccination on 675 recovered cases at varying periods after the appearance of the small-pox eruption yielded a positive take in one case

only which was vaccinated on the second day of the small-pox eruption. It would seem unnecessary to pursue further the consideration of this line of experiment and simply to multiply instances of general conformity with small-pox with occasional lapses from the rule.

Experiments on Animals.

If alastrim, and here I use it simply as a convenient term, is to be regarded as essentially identical with small-pox, one would expect it to show certain constant and distinguishing features which the latter disease has always exhibited when attempts are made to transmit it directly to animals by cutaneous inoculation. The rule is that monkeys are readily infected with material from the human lesion at the first trial, while calves and rabbits fail to react under the same circumstances. Adaptation to the calf is generally secured by repeated passage, starting with potent material from the monkey or occasionally from the rabbit. By a passage is here meant the cutaneous inoculation of scurfy material and cutaneous debris scraped from the abortive site on another calf, the final result being a crop of definite and typical vesicles indicating complete adaptation. There is a considerable element of luck in securing variolisation of the calf and the necessary passages may sometimes be quite few, but it is evident that before adaptation can be established the virulence of variola for the calf requires to be steadily raised. Once adaptation is secured, however, repeated passage tends, as is well known, to a weakening of the virus, and other methods have to be employed, such as revaccination, to restore its activity for commercial purposes. This subject is the peculiar province of the lymph specialist and need not be discussed here.

Monkeys.

The records of experimental work with monkeys to receive notice here will be those of Green, Leake and Force, and Blaxall, representing respectively Australian alastrim, West Indian alastrim, and English mild small-pox. Green (1915), in the course of his investigation at the Lister Institute, London, of material forwarded from the New South Wales outbreak of 1913, inoculated eight monkeys, all of which reacted at the first trial with production of vesicles "resembling vaccine vesicles so closely that it was impossible to distinguish one condition from another." Leake and Force (1921), of the United States Public Health Service, examined at Washington material transmitted from West Indian foci (Jamaica and Haiti). They inoculated two monkeys with crusts from Haitian alastrim and pustule contents from Jamaican alastrim with the result that the shaved areas of skin into which the materials were rubbed presented in the course of some days a vesico-papular eruption "similar to that produced in three monkeys which had been inoculated some months previously with pustule contents from a case of small-pox in the district of Columbia.

Blaxall (1923), of the Government Lymph Institute, Hendon, communicated to a Paris conference in connexion with the commemoration of the death of Jenner a very important and extensive series of observations, not so far published in English, on the small-pox prevailing in England in 1922. The material he examined came from suspected cases of the mild small-pox occurring in the north (three deaths in 821 cases) and also from the small outbreak of virulent small-pox which occurred in London and vicinity in the autumn of the same year (24 deaths in 74 cases). Samples from 12 cases of the mild type were inoculated in duplicate on monkeys. By the fourth day were observed papules which by the sixth, seventh, or eighth day had become definite and typical vesicles. Control experiments with material from suspected varicella produced no lesion. With the material from the London outbreak a vesicular eruption similar to that from the mild small-pox material presented itself on the seventh day and was harvested on the eighth day.

Calves.

Cleland and Ferguson (1915) in connexion with their investigation of material from the New South Wales outbreak of 1913, made experiments on six calves. Apparently they got some slight form of take at the first transference of human material to the calf, but it appears from the actual description that little more than a zone of redness round one of the scarified areas resulted. Scraped material from this calf yielded no result on a fresh calf. At the third and fourth removes, however, definite evidence of vesiculation was obtained and in all later removes the reactions were "indistinguishable from those of vaccinia." Green (loc. cit.), with the imported material from Australia, had a somewhat different experience with the eight calves on which the tests were made. Three calves, A, B, and C, inoculated with human material, showed at 120 hours along the lines of inoculation a series of yellow vesicles which in appearance did not resemble ordinary vaccine vesicles, being smaller and more discrete. They represented, on the other hand, too advanced a reaction to expect as a first result of inoculation of variola on the calf. Calves D and E inoculated in one spot with material from A failed to show any take, while inoculation on another spot with material from B gave suggestive "but not convincing poor-class vaccine vesicles." Calves F and G inoculated with material recovered from a monkey which reacted yielded "moderately fair quality vaccine vesicles." Green concluded that the Australian disease differed from vaccinia in its lesser ability to produce typical vaccinal vesiculation, though it approximated more closely after passage through the monkey. On the other hand, it differed from variola by the fact of its greater facility for vesiculating on the calf. In Blaxall's (loc. cit.) experience with English mild small-pox, calves completely failed to react at the first trial. So also did calves inoculated with material from the severe London outbreak. Starting with monkey material, however, he succeeded in variolising the calf by persistent passage from calf to calf of material from apparently abortive sites. At the third remove the originally abortive reaction had changed to a typical Jennerian vesicular eruption. Precisely similar variolisation was achieved with material from the London cases.

Rabbits and Guinea-Pigs.

Green failed to obtain any result by direct transference of material to 70 male guinea-pigs inoculated on the scrotum while 70 controls inoculated with vaccinia reacted typically. Leake and Force with West Indian alastrim obtained either negative or abortive reactions in two rabbits. They were, however, later found to be almost completely immune to vaccinia. Blaxall's extensive series of rabbits inoculated with English mild small-pox showed no vesiculation but only what might be termed a mild degree of papulation. With scurfy material scraped from these rabbits, especially when bleeding points were noted underneath the scabs, he succeeded in securing typical vesiculation at the third calf remove. In the course of this passage work he became impressed with the fact that only when bleeding points were observed under scabs in otherwise completely abortive sites was the material removed generally calculated to yield enhanced reactions at further removes.

Cross-Immunity Experiments.

These experiments have usually been concerned with the vaccination of animals at some time after recovery from a successful inoculation with alastrim material. Naturally, many factors have to be borne in mind in appraising such experiments, notably the time at which the subsequent vaccination is performed, the degree of the primary or immunising reaction, the potency of the vaccine lymph employed and probably many others. Variations in one or more of these categories may account for discrepancies in the observations of different workers. I enter here in tabular form Green's cross-immunity experiments

with Australian alastrim. They were performed on monkeys which were divided up into three lots, one receiving a primary inoculation of alastrim, a second of vaccinia, and a third of ordinary variola. The lots (containing, unfortunately, small numbers in each) were then tested subsequently with the reciprocal materials.

The dates of the test inoculation ranged from six to 18 days after the full development of the primary rash, which varied in intensity in the different animals.

Primary inoc.	No of animals.	Subsequent test.		
		Vaccinia.	Variola.	Alastrim.
Australian alastrim ..	8	7 (all +)	5 (4 + 1 -)	
Vaccinia ..	4	1 (-)	3 (all -)	3 (2 + 1 -)
Variola ..	5	5 (2 + 3 -)		5 (3 + 2 -)

The table shows that the Australian disease conferred practically no immunity to vaccinia or variola, that vaccinia protected against Australian disease in 25 per cent. of the cases, and that variola gave immunity to Australian disease in 40 per cent. of the cases. Also, while vaccinia protected against variola in 100 per cent. of trials, variola protected against vaccinia in 40 per cent. only. Cleland and Ferguson, who employed calves, came to the conclusion, which is not quite warranted from the actual experiments, that Australian disease and vaccinia are mutually more or less completely protective against each other, but they add the proviso "provided sufficient area is inoculated."

Blaxall's cross-immunity experiments with monkeys showed unequivocally that English mild small-pox gave protection to vaccinia. The interval between primary inoculation and immunity test with vaccinia was generally one week. With calves, as the variolisation process went on, subsequent vaccination led to less and less reaction, and the calves which showed at the third remove typical vesiculation from mild small-pox were found to be completely immune to vaccinia. Converse experiments were also carried out by Blaxall, calves and rabbits being inoculated with vaccinia and subsequently tested with mild small-pox material. Vaccinia gave complete protection. Allergic tests were also made by Blaxall on rabbits, about a week after scarification with vaccinia. Intracutaneous inoculation at that period of mild small-pox material, whether boiled or unboiled, yielded typical allergic reactions. Varicellar material failed.

Summary.

(1) Mild small-pox behaves like ordinary small-pox when transferred directly to the monkey. (2) Direct transference to calves and rabbits is uncertain and is most likely to fail, though the chances of securing some sort of atypical take at the first attempt would appear to be greater than in the case of variola. There may doubtless be slight differences between the various alastrims with respect to their animal affinities. (3) Variolisation of the calf can be accomplished by the usual passage methods. (4) Allowing for certain peculiarities which distinguish the experiments with Australian alastrim, there would seem to be no doubt that the mild small-pox of English origin behaves in all important respects like ordinary variola.

Conclusion.

The persistently non-toxic and non-lethal character of the prevailing small-pox is consistent with the view that the virus concerned is merely a variant of variola whose toxic properties for the human organism have become suppressed, while its affinities for other animal species have not appreciably changed. The intrinsic and epidemiological peculiarities of mild small-pox suggest tempting analogies with certain features exhibited by non-toxic or non-virulent varieties of bacteria generally, which recent research on bacterial variation has disclosed.

(Continued at foot of next column.)

A VISIT TO CULION LEPER COLONY, PHILIPPINE ISLANDS.

BY A. R. J. DOUGLAS, M.D., B.S. LOND.,
F.R.C.S. ENG.,

CHIEF MEDICAL OFFICER, BURMA RAILWAYS, RANGOON.

II.

IN a previous article (THE LANCET, Jan. 17th) I described the general features of the Colony and discussed the difficult question of the segregation of lepers. I now deal with the treatment as practised at Culion Island under three headings: chemical, pathological, and actual.

(1) *The Chemical Section.*—The chemical section at Culion is a development from the clinical work on leprosy which has been carried on for many years at the Bureau of Science, Manila, and is in charge of a chief chemist, G. A. Perkins, working with two junior chemists and four laboratory assistants. The chemical work includes the factory where the ethyl esters of chaulmoogra and other preparations for the treatment of leprosy are made, and the chemical laboratory and office. The chemical laboratory and office occupies a room in the same building as the other laboratories. Here the more refined tests in connexion with the manufacture of drugs are carried out and special research work carried on.⁵

The work in the chemical laboratory at present is based on the idea that the chaulmoogra group of oils are supposed to have two actions on leprosy. (1) A non-specific action, which is also produced by oils not belonging to the chaulmoogra group, such as olive oil, soya bean oil, &c.; and (2) a specific action, which is indicated by the special bactericidal action which chaulmoogra oil has on the acid-fast group of bacilli.

In connexion with the non-specific effect the chemical laboratory is coöperating with the chemical and pathological section in the use of various oils and in chemical blood analysis. With regard to the specific effect, an attempt is being made to produce substances having an increased specific action by preparing modification of chaulmoogra and hydno-carpic acid.

(2) *The Pathological Section.*—The present staff consists of three medical men, one confining himself chiefly to routine bacteriological work, a technical assistant trained in clinical microscopy, and a pathological technician, a clerk and laboratory helpers. The chief pathologist had, until early in 1924, served as acting chief physician, and had taken very little part in the actual work of the section. The present laboratory was made available early in 1923. It has working space for four workers, in addition to the

technical staff. It is fairly well equipped for routine and research in pathology, bacteriology, immunology, and ordinary clinical microscopy.

Pathology.—There being more than 500 deaths per year, the great majority of which could be autopsied, it is necessary to select cases. This is done primarily for diagnosis, the clinical staff requesting autopsy on all cases in which the condition is unusual or the cause of death in doubt. The pathological staff also autopsies, on its own initiative, other cases of special interest to itself. From April 1st, 1922, to June 1st, 1924, practically 400 post-mortems have been made, the great majority by one man. The rate will be increased somewhat in the future, as two men are now available for this work. Of actual pathological research little has been done as yet, except study of the localisation of *B. lepræ* in the organs.

Bacteriology.—The bulk of bacteriological work consists of routine smears for *B. lepræ* in connexion with the admission of new cases, and particularly cases that are becoming or have become "negative"

of veins. Such cases were transferred to the ethyl ester groups. Before the end of the year the ethyl esters became the accepted general treatment. The number of cases was increased to over 1000 by the end of the year, and to over 1600 in April, 1922, when the work was expanded to its present scale.

The total medical staff, not including the chief of the colony, is now 17 physicians; 11 of these, with an equal number of nurses, are organised into two clinic groups, which administer practically all the anti-leprosy treatments to the 4000 and more patients on the treatment lists. One of the physicians in each clinic is appointed a supervisor. Each of the nine unit physicians attends to the medical care of the 400 to 500 patients on his list who become sick and require to be sent into hospital. The General Hospital, in charge of three other physicians, contains 250 beds, and here are treated the actually sick members of the, roughly, 1000 inmates who are too advanced in leprosy, tuberculosis, or nephritis to receive active anti-leprosy treatment.

Group of 225 negative lepers waiting the completion of six months' "negative period" before their release.

under treatment. The latter requires particular attention, to avoid error both in their original inclusion in the "negative list" and their continuance therein; the clinical staff re-examines them periodically.

(3) *The Actual Treatment as Carried on in the Clinics and Hospital Wards.*—In the earlier years little could be done with regard to the treatment of lepers at Culion, other than palliative work directed by a very insufficient staff. Chaulmoogra oil by the mouth being very slow in action and too irritating to the stomach, efforts were made to use it by injection. The first advance was the so-called Heiser-Mercado formula; the Jeanselme formula (1 part chaulmoogra and 1 part of a mixture of guaiacol, M59; camphor, M259; and oil of vaseline, M59) was also used, but much less. At first the Mercado mixture was found very irritating, but now, as prepared with refined oil, is much less so. Next, in 1920, Dr. Perkins⁷ prepared the sodium salts of chaulmoogra and cod-liver oils, and these were used on a small scale. A dilute "colloidal" emulsion similar to the collobasis of chaulmoogra oil of danise was also tried.

Five hundred favourable cases were now selected, and on July 1st, 1921, treatments were begun. The cases were divided into four groups: (1) sodium gynocardate A intravenously, 50 patients; (2) sodium morrhuate intravenously, 50 patients; (3) Mercado mixture intramuscularly, 100 patients; and (4) chaulmoogra ethyl esters intramuscularly, 300 patients.

All treatments except the Mercado were given twice a week. Soon it became necessary to discontinue the intravenous treatments because of obliteration

Treatments Used.

The chaulmoogra ethyl ester is the principal medicament used since late 1921. This is given intramuscularly, and in all but a comparatively small group but once a week. The iodised preparation with 0.5 per cent. iodine has proved somewhat less irritating than the plain drug, and it is now being given to a majority of the cases.

Cod-liver oil esters have been used in a few cases. They have proved not inefficient, but are less useful than the corresponding chaulmoogra product.

Mercado mixture has been given to a small number of patients to whom the ethyl esters were particularly irritating, and to a few who refused to take any other treatment. A few small groups have been put on ethyl, propyl, butyl, and amyl esters of chaulmoogra, and on ethyl esters of certain other oils.

*Antimony.*⁸—Tartar emetic injections and Castellani's formula by mouth have been tried for a short period but with injurious results.

Various creosoted preparations were also used, and now creosoted ethyl esters are being used for extensive test.

Adjuvant Medication.—Very little adjuvant medication as a part of the regular treatment has been given until recently. A consequence of this is that the main results that have been obtained are ascribable to the injections alone.

Cases under Treatment.—The data from the cases under treatment are from the last (second) semi-annual reports rendered by the treatment physicians, dated March 21st, 1923. These reports, it may be

⁷ Reports of Philippine Health Service for 1920, p. 41, and for 1921, p. 128.

⁸ Rodriguez and Enbanas: The Treatment of Leprosy with Antimony, Phil. Jour. Sc., col. 28, No. 6, December, 1923.

remarked, involve much work, and it requires two or three months to obtain the data and reduce them to a usable form. In 1922, in dealing with the figures supplied by the physicians in charge of the nine different units, it was found that the results varied very much in the different units. This was found to be due not only to the personal equation of each physician but also to the differences in classifying the types of case and in recording the degree of involvement of the tissues by the disease, and the degree of advancement of the disease where evident.^{9 10}

The necessity of taking active measures to secure more uniform reporting by individual physicians having been made clear, detailed instructions were prepared and distributed, using certain tentative classifications, it being understood that they were subject to revision later on.

Number under Treatment.—During the period referred to there were in round numbers 4200 patients under treatment. Since then 700 have had to be dropped from the treatment lists on account of nephritis, tuberculosis, &c., while some 300 new cases have been taken on. Patients not on the treatment clinic lists report to a dispensary clinic from time to time, and when necessary are hospitalised in the General Hospital, which is separate from the wards for "treatment" patients.

Sex.—Of 3975 cases tabulated 65.1 per cent. are males and 34.9 per cent. females, a curious proportion that has been repeatedly observed in leprosy.

Age.—Practically 70 per cent. of the 3975 cases are at the present time between 15 and 46 years of age. The smallest group, 35 to 40, is 9.8 per cent. of the whole; the largest, 20 to 25 years, is 17.7 per cent.

Duration of the Disease.—Of 3852 cases tabulated in this connexion only 15 claimed to have had the disease less than a year at the time of the report. The largest group claimed 5 to 7 years' duration. Roughly the average duration was between 8 and 8.5 years.

Types of Cases.—Of 3888 cases, practically 22 per cent. are recorded as of the cutaneous type, 69 per cent. as mixed, and 9 per cent. neural. This great predominance of the mixed type is due in part to the average long duration of the disease, and in part to the very careful search made for evidences of disturbed nerve function.

Relation of Type of Case to Duration.—It may be noted that there is a much higher percentage of pure cutaneous cases among those of short duration than among the chronic cases. On the other hand, pure neurals are much more common among those of longest duration. There is evidenced a distinct tendency to shift from pure cutaneous to mixed, and finally, among those surviving, for the cutaneous manifestations to disappear.

Results of Treatment.

Space will only allow of a brief presentation of the gross results and the factors that apparently affect them.

Gross Results.—Of the total of 4035 cases of all kinds and degrees of advancement, under all varieties of anti-leprosy treatment included in the last semi-annual reports, the present status as compared with the original condition is: Improved, 53.3 per cent.; stationary, 36 per cent. (totalling 89.3 per cent.); worse or dead, 10.7 per cent. Taking the improved as a separate group, 7.5 per cent. are reported as markedly improved, 20.9 per cent. moderately improved, and 71.7 per cent. but slightly improved.

These gross results must be considered with an appreciation of the influence of certain modifying factors. These are of two types—those independent of the material used, and those that are to a greater or less extent influenced by the medicament. The former includes sex, age, duration of the disease,

type of case, and time under treatment. Also, of course, the personal equation of the physician, but in so large a group these tend to neutralise each other.

Sex.—Males have improved to a slightly less extent than females—52 per cent., as compared with 55 per cent.

Age.—When the percentage of improved in each five-year group is laid down in a graph for the two sexes separately, the resulting lines show certain fluctuations and in places wide differences, probably corresponding with periods of greatest sexual activity and the menopause.

The statistics would seem to bear out the opinion of the individual treating physicians that marriage is harmful for lepers.

Duration of the Disease.—This has a very decided influence. Of the group (261 cases) claiming two to three years' duration, 68 per cent. have improved; whereas those of 15 to 20 years' duration (266 cases), but 43 per cent. have improved. In keeping with this there are relatively fewer marked improved in the older groups.

Type of Case.—This factor, as has been said, is to a considerable extent dependent on duration, the cutaneous respond best. Of the cases of the cutaneous type, 62 per cent. have improved, of the mixed 49 per cent., of the neural but 39 per cent. The neurals, by the way, have also the lowest worse figure. The percentage of stationary cases varies in reverse order, the neurals having the largest.

Time under Treatment.—This is naturally an important factor. But 35 per cent. have been a full year with 75 per cent. improved. For those treated less time the figures are much lower.

The factors that are influenced by the medications themselves are the number of injections given during a given period, the total amount of drug administered, and the reactions that occur during treatment. A bland medicament can be given more frequently, more regularly, and in larger doses.

The Number of Injections that a patient is given and the dosage are limited by the individual reaction to injections (and these vary widely), the development of complications of whatever degree of importance, and his own desire or lack of it to receive treatment.

Total Amount Given.—As for the total amount given, one-half of all the cases received 30 c.cm. or less during the six months, whereas the minimal desired dose for average active cases for the period was 60 c.cm. Less than 10 per cent. (8.7 per cent.) received more than this amount. Correlating improvement with dosage of those that received 30 c.cm. or less but 37 per cent. were reported improved, whereas of those (33 per cent. of the whole) that received more than 40 c.cm. 73 per cent. improved. Similarly the degree of improvement increased rapidly with the increase of amount of the drug taken.

Comparison of Preparations.—On comparing the effect of the plain and iodised preparations the only real difference that has been seen is that the iodised being somewhat less irritating, relatively more patients took larger total amounts, resulting in somewhat better improvement figures. Dose for dose there is no apparent difference.

Complications.¹¹

Pulmonary tuberculosis and nephritis are the most frequent causes of death in Culion, and offer serious problems in connexion with treatment work. (Table I.)

TABLE I.—Chief Causes of Death in Treated (T.) and Untreated (UT.) Groups of Patients, 1922-23.

Group.	Total number of deaths.	Tuberculosis.	Nephritis.	Heart disease.	Pneumonia.	Gangrene septic infections.	Dysentery and enteritis.	Leprosy.	Cerebral hemorrhage.	Malaria.	Other diseases.
T.	282	91 (32.2 %)	74 (26.2 %)	28 (9.9 %)	19 (6.7 %)	9 (3.1 %)	9 (3.1 %)	7 (2.4 %)	6 (2.1 %)	6 (2.1 %)	32 (11.3 %)
UT.	415	309 (74.4 %)	41 (9.8 %)	26 (6.2 %)	9 (2.1 %)	4 (0.9 %)	2 (0.4 %)	11 (2.6 %)	7 (1.6 %)	1 (0.2 %)	5 (1.2 %)

⁹ Report to the Director of Health on the Reorganisation and Activities of the Medical Section, Culion Leper Colony, and of the Results obtained from the Treatment Work, 1922. By H. W. Wade, M.D.

¹⁰ Leprosy Work in the Philippines. By H. W. Wade, M.D. Trans. of the Fifth Conf. of the Far East Assoc., 1923. Now in the press.

¹¹ An article by Dr. C. B. Lasa, Chief Physician, and Drs. B. de Vera, J. G. Samson, and F. C. Eubanas, of the Medical Section, Culion Leper Colony, "On the Chief Causes of Death Among Lepers at the Culion Leper Colony," will shortly be published.

Tuberculosis.—Death from all forms of tuberculosis in Manila in 1921 constituted 19.9 per cent. of the total deaths. In 1921 the Cullion rate was 32.0 per cent., distinctly higher than the corresponding Manila figure. In 1922 there was a sudden increase to 51 per cent., and in 1923 to 46 per cent. of the total deaths. This is ascribed to the irritating effect of ethyl ester treatment lighting up latent tuberculosis.

Nephritis.—Nephritis shows a much higher percentage in the treated than in the untreated. Directly or indirectly—probably both—the general and systematic application of the ethyl ester treatment gives rise to an intensification of the mild processes in the kidneys which are admitted by many authorities to be quite common in leprosy, and which we believe are frequently not sufficient in themselves directly to lead to a fatal outcome.

TABLE II.—*Analysis of Reports of Treatment, March to September, 1923.*

Drug.	Number.	Improved.	Stationary	Worse.

A table is also appended (Table II.) of the analysis of reports of treatment from March to September, 1923, but no detailed comments similar to those for the previous half-year are given.

Conclusions.

It is frequently asked whether one preparation is appreciably better than another. It is too soon to make any definite statements; probably at least another two years must elapse before it will be safe to make a dogmatic statement as to the value of the ethyl ester treatment with its various modifications. It is probably not even safe to say at present that the ethyl ester injections are of appreciably greater value than the intramuscular injection of refined chaulmoogra oil itself, but the figures are distinctly encouraging.

Both the impressions of the staff and patients and the statistical data indicate that the treatment is, on the whole, productive of much benefit, and is distinctly promising in those cases that are not too advanced or too badly affected by complications for marked or permanent relief to be expected. Among those whose treatment has been of less than one year's duration a comparatively low percentage are reported as improved, while of those of the one- or two-year group a high improvement rate of about 70 per cent. is shown. The amount of the drug given is also of great importance. Probably any treatment which is not likely to be continued regularly for at least two years is waste of time and money. Some patients show hardly any improvement for nearly a year, and then begin to make progress. This has to be taken into account in dealing with any uneducated and comparatively ignorant population who are undergoing *voluntary treatment* and who are likely to become impatient and give up treatment because the improvement hoped for is delayed.

On the other hand, treatment is likely to be abandoned because they consider that the improvement is so great that they are sufficiently cured. The publication of results drawn from the statistics of small numbers of patients (200 or 300, say), treated for short periods of less than a year, is strongly to be deprecated as likely to lead to false deductions and future disappointment.

Finally, it cannot be said that “a new cure” has been discovered for leprosy, but a good deal of research is being carried on, and it is hoped that one day a cure will be discovered (possibly on quite different lines) that can be described with truth as a specific for this disease.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Vital Statistics of the Irish Free State.

SPEAKING at a recent meeting of the Section of State Medicine of the Royal Academy of Medicine in Ireland, Sir William Thompson dealt with a few outstanding points in connexion with the vital statistics of the Irish Free State. He said that nearly 72 per cent. of the population of Ireland, according to the census of 1911, covering about 84 per cent. of its area, came under the jurisdiction of the Government of Saorstát Éireann as the result of the Treaty. The population of Saorstát Éireann, which was 6,547,652 in 1841, fell to 3,139,688 in 1911, that of Northern Ireland falling from 1,648,945 to 1,250,531. According to the census of 1911, about 27 per cent. of the population of Saorstát Éireann area was urban, while the urban population of Northern Ireland constituted about 47 per cent. of its total population. The marriage-rates in Saorstát Éireann for the various periods from 1871 to 1914 showed a decided tendency upwards, increasing from 4.38 per 1000 of the population in 1871–80 to 5.02 per 1000 in 1911–14, but rising to 5.06 in 1919–22. As might be expected, the crude birth-rate was low (19.49 per 1000 in 1923) as compared with England and Wales and Scotland, but a wide disparity existed in regard to the fertility-rate; in Saorstát Éireann the number of legitimate births per 1000 married women, aged 15–45 years, was 305, as compared with 197 for England and Wales. The death-rate from all causes, which was 17.64 per 1000 as the annual average for the years 1891–1900, fell to 13.34 per 1000 in 1923, the latter being the lowest rate recorded. The mortality from tuberculosis was 2.53 per 1000 of the population for the ten years 1901–10. The rate for 1923—i.e., 1.41 per 1000—showed a reduction of 1.12 per 1000, or 44 per cent. The rate represented by deaths from cancer rose from 0.37 per 1000 for the period 1881–90 to 0.81 per 1000 for 1911–14, since which period the mortality from cancer had remained practically stationary. The mortality from diabetes in Saorstát Éireann during the five years 1919–23 was 0.7 per 10,000 of the population as compared with 1.1 for Northern Ireland and England and Wales. Infant mortality, which was 99 per 1000 births during the decennium 1891–1900, was only 66 in 1923, the lowest rate recorded, the rates for Northern Ireland, England and Wales, and Scotland during the latter year being 77, 69, and 79 respectively. The infant mortality relating to urban areas in Saorstát Éireann was 99 per 1000 births in 1923, which is nearly double the rate (50) for rural districts.

Although the mortality among the infants whose births were legitimate was low (59 per 1000), that among the births of illegitimate infants must be considered excessive for the year 1923—viz., 344 per 1000 illegitimate births. In regard to this high rate, he pointed out, it should be borne in mind that in the absence of information relating to preceding years, and in view of the smallness of the numbers from which it was derived, it was possible that the period under review (1923) might not be a typical year.

Medical Referees to the National Health Insurance Commission.

It was stated in this column a fortnight ago that appointments of medical referees to the National Health Insurance Commission were to be made on the advice of a Selection Board set up by the Civil Service Commission. This is being done, but the Selection Board is so in name only, for it consists of three permanent medical officials of the civil service. The promise was made many years ago by the National Health Insurance Commission that when referees were to be appointed, the representatives of the profession would be consulted as to the suitability of the candidates. It was recognised that if the referees were to perform their duties effectively, they must be persons of such character and experience as to command the respect and confidence of the profession. Recently, when sanction was given to the appointment of referees, the medical members of the Advisory Committee to the National Health Insurance Commission were assured that the Irish Medical Committee would be invited to nominate one or more members of the Selection Board. Subsequently, this decision was reversed and a purely official board was appointed. This action, it is feared, will prejudice the efficiency of the referee system.

An Unintended Slight.

In the paragraph dealing with the terms of appointment of the referees in THE LANCET of Jan. 10th (p. 95), by unfortunate wording a slight appeared to be cast on the importance of the duties of the medical inspectors of the Department of Local Government and Public Health. It was intended to say that the duties of the latter were not "more exacting" than those of the medical referees whose salary was under discussion. Unfortunately, the word "more" was omitted, and the sentence stated that the duties were not "exacting." The work of a Local Government inspector is, of course, not only exacting, but important and responsible in a high degree.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdr. J. MacDonald is placed on the ret. list, with the rank of Surg. Capt.
W. A. Hopkins to be Surg. Lt.

ROYAL ARMY MEDICAL CORPS.

Maj. and Bt. Lt.-Col. M. G. Winder to be Lt.-Col., vice Lt.-Col. W. M. B. Sparkes to ret. pay.
Capt. T. F. Kennedy relinquishes the temp. rank of Maj., on ceasing to be empld. as a Dep. Asst. Dir. of Hygiene.
Capt. W. H. Ferguson relinquishes the temp. rank of Maj., on ceasing to be empld. as a Dep. Asst. Dir. of Pathology.
Capt. H. G. Hobson is restd. to the estab.
Lt. (on prob.) F. H. King resigns his commn.

ARMY RESERVE OF OFFICERS.

Surg. Lt.-Col. J. H. Power (Life Guards), having attained the age limit of liability to recall, ceases to belong to the Res. of Off.

Army Dental Corps.—Lt. J. S. Lycett, late 71st (W. Riding) Fd. Bde., R.A., T.A., to be Lt.

TERRITORIAL ARMY.

Maj. W. P. G. Williams (I.M.S. retired) to be Major.
Maj. (Prov.) H. L. Garson is confirmed in his rank.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Capt. P. J. Watkin, from Active List, to be Capt.

INDIAN MEDICAL SERVICE.

Maj. W. D. H. Stevenson relinquishes the temp. rank of Lt.-Col. on vacating the appt. of Assist. Director-General.

TESTIMONIAL TO PROF. RUTHERFORD MORISON.

The first subscription list to this testimonial appeared in THE LANCET of Jan. 17th. Further subscriptions may be sent to the hon. secretary and treasurer, Mr. R. J. Willan, F.R.C.S., 6, Kensington-terrace, Newcastle-on-Tyne.

Correspondence.

"Audi alteram partem."

ALASTRIM, PARA-SMALLPOX, AND VARIOLA.

To the Editor of THE LANCET.

SIR,—My interest in Prof. Jorge's masterly paper has equalled that of your correspondents, but I fear that too great attention is being devoted to the mere question of terminology, whereas the essential question is "What practical steps are necessary to deal with the small-pox of to-day, call it what you will?" I do not agree with the dictum that attempts to treat outbreaks of the present non-virulent strain of small-pox just as if it were a virulent strain tend to bring administrative action into contempt and disrepute. This is only true if the opportunity is missed, through mischance or defective administrative machinery, of dealing promptly and efficiently with the initial cases. My warrant for making this ex-cathedra statement springs from an experience of 38 years in a city and port now containing over 385,000 persons, and during this time I have had to deal with 85 introductions of small-pox, ranging in fatality from 2.9 per cent. upwards.

In 1904 an extraordinarily mild type of small-pox, conforming to the Gloucester type (with which I am acquainted), was brought into Bristol on six occasions, got amongst some dockers' huts at Avonmouth, and threatened trouble. While we marvelled at the abnormal mildness, at the tendency to abort, at the absence of secondary fever, and so on, this was not allowed to interfere with our plain administrative duties of control at the outset, and the total of cases was limited to 34, with only one death of an unvaccinated infant. About the same time (1903-04), I note, Leicester experienced a similar mild outbreak, leading to 321 cases and four deaths. Nor was the mildness of our Avonmouth type to be trusted—one patient carried the disease to South Wales where 15 cases, 4 confluent, and one death resulted.

I deprecate the suggestion that text-books tend to over-emphasise the heavy fatality of small-pox; it is impossible to exaggerate the risk when the malignant type is in evidence, as I well know from many pitiful experiences. Malignant small-pox is not played out, witness the recent experience of Michigan,¹ and it is unwise to encourage a feeling of false security.

I am, Sir, yours faithfully,

D. S. DAVIES,

Medical Officer of Health, City and County and Port of Bristol.

Jan. 17th, 1925.

To the Editor of THE LANCET.

SIR,—I think Dr. R. P. Garrow has hit the nail on the head. The Gloucester epidemic was *de facto* not small-pox, but yet it was related to small-pox, and this relationship should certainly be brought out in whatever nomenclature we finally determine to adopt. Exotic neologisms like *alastrim* or *amaas* simply confuse the issue; let us call this mild distemper *para-smallpox* or *para-variola*, on the analogy of *para-typhoid*. Having then thus fixed the fact of relationship, we may begin to consider more seriously than we have yet done what relationship actually involves. Does it not, in fact, mean that there is or can be (varying with time, place, &c.) a certain *coming and going* between the members of these disease-groups—thus within the varioloid group, the influenza-encephalitis-myelitis group, &c.?

I am, Sir, yours faithfully,

Edinburgh, Jan. 14th, 1925.

A. J. BROCK.

¹ The Medical Officer, Dec. 13th, 1924. Supplement, p. 7.

INFECTION SPREAD BY VAGRANTS.

To the Editor of THE LANCET.

SIR,—I am thankful to see from a paragraph in your issue of Jan. 10th that you desire the Ministry of Health to act promptly on the information given in the recent Official Survey of the provincial casual wards. A case before the Tavistock magistrates, reported in the *Western Morning News* of Jan. 6th, shows how tramps are treated in some wards notwithstanding the Official Survey has been made and published. A "casual" was prosecuted for damaging a lock in the Tavistock ward. The master said "that he made a complaint about not having his jacket fumigated. There were no grounds for complaint because they could not fumigate clothes on a Sunday." The prisoner used his jacket as a pillow because no pillows were provided.

Now, the regulations of 1882 (as stated in your paragraph) require that the casual's clothes should be taken from him, and, if necessary, dried or disinfected. And they make no exception for Sunday. Indeed, a garment is just as infectious on a Sunday as on a week-day. I take it as quite clear that the garment needed fumigation or the master would have told the justices that it was not necessary. No information is given in the report as to why fumigation was necessary, but I see in the *Poor Law Officers' Journal* of Jan. 16th that one of the Tavistock guardians said that "many of the men who tramped the country were covered with vermin." At all events there is no doubt that the regulations requiring disinfection are essential both for the safety of the public and of the inmates of the next ward to which the wayfarers come. And a man in verminous clothes is much hampered in his search for work.

I am blaming the guardians not the master; because it is the guardians who should have supplied the means of disinfection on Sundays and the pillows, and no doubt the master out of humanity allowed the man to sleep on his jacket. I believe in some cases the "paupers" are allowed to sleep with their boots for pillows. In some cases where there are hammocks they are so unsatisfactory that the men prefer to sleep on the floor using the hammocks as bedding.

I hope that some of the health authorities will move. I have just written on the subject to the councils of the counties mentioned in the Survey as having from one-sixth to one-third of their wards unheated, and to those where the cleanliness is said to be "poor" and some others. I shall be happy to send a copy to any other county council or any district council who would care to have it. As far as I can see from the Survey the Devonshire casual wards seemed to be among the worst; for out of the 15 wards in England and Wales where the cleanliness was said to be "poor," four belong to that county; and also it and Dorset are the only counties which had as many as one-third of their wards unheated. It is fair to Tavistock to say that their ward was heated.

I am, Sir, yours faithfully,

J. THEODORE DODD,
Barrister-at-Law and ex-Guardian.

55, St. Giles', Oxford, Jan. 17th, 1925.

INTRAVENOUS INJECTIONS IN NON-TUBERCULOUS MENINGITIS.

To the Editor of THE LANCET.

SIR,—I was impressed with the lucidity displayed by those who took part in the recent discussion on Non-tuberculous Meningitis at the Royal Society of Medicine (THE LANCET, Dec. 20th, 1924, p. 1281). It seemed to me that a fresh aspect of the case was indicated by Dr. D. Nabarro, who dwelt on the factor of a general septicæmia in a number of cases of meningitis. This recalled to my mind a paper I heard read in the recent French Congress of Oto-Laryngology in Paris by Dr. Maloens, of Brussels. His observations lead him to attach great value to the administration of an iodo-urotropin preparation. At first he

used it by the intrathecal method, and in proof of its value narrated a case of typical otitic purulent meningitis in which recovery was brought about. More recently he had become convinced that intravenous injection preceded each time by lumbar puncture secured the entrance of the remedial agent into the intrameningeal spaces, and he cited a case in which he had pursued this course—namely, one of diffuse purulent meningitis subsequent to an acute influenzal labyrinthitis in a woman of 25, in which "in spite of the extreme gravity of the prognosis (Mygind), he observed in addition to a characteristic fall of temperature and a progressive attenuation of the clinical symptoms, a parallel improvement in the characteristics of the cerebro-spinal fluid and complete recovery." The paper containing a full statement of the experimental researches by various investigators which had led the writer to adopt the intravenous in place of the intraspinal method of injection, is to be found in *Bruxelles Médical* for Nov. 16th, 1924. Although the method is intended to bring about the local action of the remedy on the contents of the meningeal spaces, it is at the same time well calculated to combat the general septicæmia to which Dr. Nabarro alluded.

In the treatment of such a fatal disease no suggestion can be lightly thrown aside, and this is my excuse for drawing attention to Dr. Maloens's views.

I am, Sir, yours faithfully,

JAMES DUNDAS-GRANT.
London, Jan. 16th, 1925.

"ELECTRONIC REACTIONS."

To the Editor of THE LANCET.

SIR,—I can only speak for myself, but I imagine that a number of other members of the Medical and Electro-Therapeutical Sections of the Royal Society of Medicine would agree with me that the communication of Sir Thomas Horder of Friday must certainly rank as one of the most extraordinary and tantalising communications that has ever been presented before a scientific society. As there was no time left for discussion, and discussion at a later date was not at present desired by those at the meeting, I can only hope that you, Sir, will allow a few comments through the columns of your journal.

Sir Thomas Horder disclaimed responsibility for the report except for a fifth share. But while on the one hand he emphatically declared for the final deposition as false gods of the oracular Abrams boxes, his acute diagnostic instinct might have warned him that the effect on the lay public and on "electronists" of the encouraging gesture he made on the other hand in disclosing the 100 per cent. accuracy of certain incompletely described physical tests with Dr. Boyd's modifications, would only be to confirm in the minds of many of the public the rightness of their view that there still "may be something" in the original Abrams boxes: and so, indeed, the *Morning Post* to-day (Saturday) interprets his Committee's Report.

One can only wish publication of any report had been delayed till further detailed announcements could be made with regard to the possible scientific or medical uses or not of Dr. Boyd's apparatus, or else that at least more information had been given as to the nature of the tests and responses in Dr. Boyd's almost magical copper-gauze-lined cabinet! A 100 per cent. accuracy is almost too good to be true in most scientific work: it suggests that some simple solution for the cause of the phenomena must be there to be found if only we can trace it. I shall only suggest briefly a few matters as to which I should have liked to have had information vouchsafed, and, indeed, before a scientific meeting might, I think, reasonably have expected information given.

1. The nature and origin of the substances used in the tests? What was used besides "sulphur"? What proof, for example, was there that there was no radium present in the "active" substance? In more detail we should have heard how the "substances"

were presented to the recording complex of apparatus and boys.

2. Without reflecting on the honesty of Dr. Boyd and Miss S., one would like to know what they did, and where they stood while the tests were going on. For unconscious deception has often been found in psychical tests, and in phenomena such as "thought-transference"—almost inaudible whispering, and the like. And in the interpretation of extraordinary phenomena every factor should be sceptically scrutinised. The "N" rays hoax was an example of how eminent scientific persons can be deceived—not that deception or hoax is here suggested.

3. What the copper-gauze screen was supposed to shield the apparatus from? Were any experiments made to test whether, for example, wireless waves were reduced in amplitude in the cabinet, or neighbouring potentials or electric fields, such as those in the electric lighting circuits, were diminished or abolished? In short, what were the physical differences between the outer room and the inside of the screened cabinet?

4. Scientific experiments and results (with the rarest possible exceptions) can be duplicated at other times and in other places. Would Dr. Boyd be willing to submit his work to a London committee in London? The copper-gauze can be duplicated: are the Glasgow boys essential?

5. What interpretation does Sir Thomas Horder give for the epigastric percussion sign? He acted as what may be called the medical referee of the Committee, and some attempt at explanation might have been expected from him at a medical gathering, of his findings on the boy, and his personal sensations when acting as indicator. The epigastric note on percussion depends obviously on two factors: (1) The contents of the stomach, transverse colon, &c.; and (2) the thickness or rigidity of the abdominal wall. With rigid rectus muscles the tympanic note is masked, and the note is "duller." Now, if the boy whose epigastrium is percussed has an abdominal wall contraction when the "active" substance is presented, he must have that (1) voluntarily, or (2) involuntarily, as a result of some sign or sensation—e.g., when an electric current passed from his forehead electrode to the earthed plates on which he was standing.

Now, as currents as small as 10^{-12} ampère can be measured by Einthoven and Paschen galvanometers, and even smaller currents can be accurately estimated by almost infinitesimal differences of potential by quadrant electrometers and electroscopes (currents much smaller than those potential changes continually taking place at and near the epigastrium owing to heart contractions), it seems strange that physical measurements were not made, or at least were not given, of the probable current changes: also of their differentiation from those detectable by the electro-cardiograph. Indeed, with the refinements of scientific apparatus now available, it would seem difficult to realise what useful purpose the boy and his epigastrium can serve as an indicator! Is the boy as a "medium" or indicator more sensitive than a modern electrometer to potential differences? For Dr. Boyd's use of an "inductance" suggests that potential differences are at work in the production of his results.

In short, the whole position from the point of view of those of us (specially of the Electro-Therapeutical Section, who were invited to the meeting, and were unable to express any opinions) who do know something of electrons, and of electrical apparatus and measurements, was left most unsatisfactory, if not ridiculous. The whole matter seemed to be as yet of no medical interest, yet medical developments were hinted at; so I can only suggest to Sir Thomas Horder and his Committee that it might be well to allow a full and unbiased investigation to be conducted by a representative committee of, say, physicists such as Profs. Sidney Russ and F. L. Hopwood, or physiologists who are familiar with physical experiments in medical subjects. Then one may hope Dr. Boyd's vaunted advance on Abrams's methods will be

removed from the atmosphere of thaumaturgy in which I, for one, felt the subject was left by the communication to the meeting on Friday.

I am, Sir, yours faithfully,

J. H. DOUGLAS WEBSTER.

Chandos-street, Cavendish-square, W., Jan. 17th, 1925.

THE GLUT OF WOMEN DOCTORS.

To the Editor of THE LANCET.

SIR,—I am sure that medical women will be grateful to Mr. W. Robinson for giving the number of applicants—namely, 78 women doctors—for a junior post open to women only at the Children's Hospital, Sunderland. His letter draws attention to such a serious state of affairs that the widest publication is necessary in order to secure a remedy. I refer to the fact that owing to the few hospital posts (junior, senior, or honorary) now open to well-qualified medical women, it naturally follows that when one post is available there will be a greater number of women candidates than a similar post when male applicants are required. I think one may safely say that 99 out of 100 posts as house physicians and house surgeons are regarded as the strict preserve of young male doctors owing to the policy pursued by the selection committees of voluntary hospitals up and down the land to exclude women doctors.

During the war there was a greater influx of both sexes of medical students to supply the needs of the nation, and the maximum was reached in 1919. In 1924 there came out a maximum of qualified men and women doctors from the medical schools. But even with this increase the proportion of the newly qualified is about one woman doctor to five men. The total registered number of medical women is somewhere about 2000 in Great Britain, and the medical men registered are about 25,000. It is also true that the number of medical students (men and women) entering the schools is returning to the pre-war level. What is really needed is fair treatment for women from the selection committees so that there is an increase in proportion of all hospital posts that are open to women. Why is it that there are so few hospitals which have appointed on their honorary staffs women doctors in charge of beds? Yet the numbers of women and children to men patients to be treated are as 3 to 1 of all patients. Pure prejudice on the part of the male colleague, I fear, must be the answer.

Public opinion has always been on the side of the women doctor, who must be allowed the same facilities to equip herself as her male colleague. With the changes that must necessarily come over hospital management and finance, the methods of appointment must also change. I am sure the day will come when the hospital patient will have the right of access to the services of a woman doctor. Every hospital which relies on an appeal to the public for support will have to see that a proportion of the honorary staff are women.

I am, of course, quite aware that Mr. Robinson's letter is meant as a deterrent and warning to parents and intending medical women candidates as threatening future unemployment for medical women. Let me tell them to take no heed of such Partingtons, for the public needs and demands medical women in many and ever-widening spheres. Our movement has too strong a hold to be pushed back, much as the reactionary would like it.

I am, Sir, yours faithfully,

MABEL L. RAMSAY, M.D., L.R.C.S. Edin.

Plymouth, S. Devon, Jan. 18th, 1925.

To the Editor of THE LANCET.

SIR,—Allow me to make some comments on Mr. Robinson's encouraging letter of Jan. 13th.

Although, since I am not in practice, the number of patients I come across is infinitesimal, still even I am frequently hard put to it, in an individual instance, to

recommend a medical woman, so lamentably few are they. The only case where there is anything like adequacy is in consultant gynaecological and obstetrical work in a few big towns. But a preponderance of women at the top of the tree by no means compensates for their lack elsewhere, or meets the growing demand for their services. So that the illumination Mr. Robinson sheds on the numbers of women practitioners in the making is highly gratifying.

A glance at the facts shows the shortage of medical women in a lurid light. Although men are accustomed to being tended by women in their infancy, and again perhaps later by women nurses, few would deny that it would be highly undesirable for them to be compelled to consult women rather than men doctors because there was no man within reach. A fortiori therefore, since women are not even accustomed in their infancy to be tended by men, they should not be compelled to consult a man doctor because there is no woman within reach. There will never be enough medical women in England till every woman is able to consult one if she so wishes. When one reflects further that the numbers of women patients are far greater than men because so many are included in the province of obstetrical medicine, one sees what a huge number of medical women are needed, and how ludicrous is the present proportion to men on the British register—i.e., roughly 1 to 20! Further, it is obvious that the supply of posts vacant can never be adequate to the demands of young graduates except at such times as that of the Great War, when everyone was seized on for work with avidity. But just as, at the cessation of the war, the Government found itself with surplus stocks of inanimate goods, so animate beings were also stranded, and unemployment is rife everywhere. Medical students preparing for service now find themselves qualified with no immediate demand for their work, just as do members of other professions.

It may be that medical women are taking rather longer than medical men to get absorbed in the general population, and here again Mr. Robinson's carefully analysed figures are very illuminating. Of the 78 applicants only 16 had London diplomas. Inasmuch as women from five or six London schools besides the provinces take London qualifications it is obvious that only a small fraction of these come from the London women's school—i.e., a school where only women are trained has very few of its students seeking work so far afield. This is what one would expect. It is natural that where women form only a small (new) proportion of graduates, their interests should not be pushed, when the staff, dean, and warden are all men. "Fellow-feeling," to say nothing of custom, tends to the forwarding of men's interests. The same applies to the boards of management of all hospitals. They are almost entirely composed of men, and tend to appoint such.

At any rate, some 30 years ago the number of women qualified to posts available was in a much higher proportion than now; and just as the members of the then "glut" have long ago resolved themselves into useful, busy, and most prosperous citizens whom the community could ill spare—so we rejoice that history is repeating itself, and that the members of another delightfully large "glut" are waiting for absorption in the same way!

I am, Sir, yours faithfully,

H. B. HANSON, M.D., B.S., D.P.H.

Circus-road Mansions, N.W., Jan. 19th, 1925.

UNIVERSITY OF VIENNA: FACULTY OF MEDICINE.—

The programme of the Sixteenth International Course of Lectures on Medicine, which is to take place in Vienna from Feb. 9th to 21st, has reached us. The course will deal with the Diseases of the Digestive Organs and their Therapeutics. A practical course following the lectures will be held from Feb. 23rd to 28th. Those taking part in the course include Profs. J. Tandler, H. H. Meyer, K. Sternberg, K. F. Wenckebach, C. Pirquet, among many others. Foreign medical men who desire to attend are asked to communicate with Dr. Kronfeld, Porzellangasse 22, Vienna IX.

Obituary.

CLEMENT DUKES, M.D., B.S. LOND.,
F.R.C.P. LOND.

Dr. Clement Dukes, for 37 years medical officer at Rugby School, had a deserved, even a world-wide, reputation as an authority on the health of the school-boy. His death occurred on Sunday last, Jan. 18th, at the age of 79.

Clement Dukes was born in 1845, son of the Rev. Clement Dukes. He received his medical education at St. Thomas's Hospital where he was a distinguished student, graduating in 1869 at the University of London with honours in medicine, and in surgery with the gold medal. After holding house appointments at St. Thomas's Hospital and at the Hospital for Sick Children, Great Ormond-street, other clinical appointments at the City of London Hospital for Diseases of the Chest and at the Royal Ophthalmic Hospital, Moorfields, he was appointed in 1871 medical officer at Rugby, which post he held until his resignation in 1908. He served under four head-masters, Canon Hayman, whose removal from office two years later was the subject of prolonged litigation, Dr. Jex-Blake, Dr. Percival, afterwards Bishop of Hereford, and Dr. James. While holding this position he proceeded to the M.D. of London in 1876 and was later elected a Fellow of the Royal College of Physicians. On his retirement he was appointed consulting physician to the school.

Dukes was the fortunate possessor of an orderly mind and great literary capacity—knowing much, he was able to record his knowledge in assimilable form. He was the author of "Health at School," which went through four editions, and remains a standard work even though developments along many lines have rendered some of his reflections obsolete; of "The Preservation of Health by Cleanliness and Temperance," which was awarded the Howard Medal and a money prize by the Royal Statistical Society; of "The Essentials of School Diet," which passed through two editions; and of "L'Hygiène et l'Éducation de l'Adolescence," which gained the silver medal of the Société Française d'Hygiène, much of the information being strikingly new to a French audience. He also wrote the articles "The Hygiene of Youth" in Allbutt and Rolleston's System of Medicine, and "Scarlet Fever and Rubella" in the Encyclopædia of Medicine, his last work being "The Fourth Disease," published in 1901 and following his attempt in the columns of THE LANCET to establish the clinical entity of a certain group of febrile symptoms accompanied with rash.

Dukes will long be remembered by his earliest work "Health at School," which had its origin in a communication to the popular compendium "A Book of Health," compiled by Sir Malcolm Morris some 15 years after Dukes had started on his life-long association with Rugby. There had been before this date many disconnected articles dealing with school health, referring in particular to positions at the great private enterprises called public schools. Many of these contributions had arisen out of particular occurrences like outbreaks of enteric, ophthalmia, or ringworm, but the subject of public school life in its general sanitary aspects had never before been considered comprehensively, with outbreaks of disease taking part in the plan as episodes requiring preventive as well as curative measures. Dukes's book was found at once to deserve careful study by parents and all school authorities, head-masters, house-masters, and form-masters alike. The sanitary construction of boarding-houses, as it was then understood, was set out as well as the need for proper attention to diet and to hours of work and play. Dukes indicated clearly that the amount of work which can be safely done may be ascertained by general rules, but that these may need in individual cases special adaptation where the collateral circumstances of the age and

health of the boys are considered. He pointed out on the subject of overwork the necessity of discrimination by the authorities upon medical advice between laziness and sickness, the symptoms of pressure not necessarily depending upon the stress of lessons, but sometimes upon disinclination and sometimes upon physical disability. He further discussed the medical arrangements for the treatment of disease in a school population and for the isolation of infections, pointing out the need for the quarantine of doubtful cases until their exact nature had been determined. The book was prepared with great care; it showed a practical knowledge on the part of the author of the subjects of which he treated, as well as prevision in directions where developments might be expected. The success of the work was as certain as it was well-earned.

His name again will in text-books be long connected with the question of the existence of the "Fourth Disease." He described in THE LANCET¹ three outbreaks of an infectious disease having characteristics sufficiently constant to entitle it to be considered an entity, and differing in definite respects from measles, German measles, and scarlet fever. Dukes's description of "Fourth Disease" was accepted at the time by many medical men as satisfying them that certain cases which had come under their care had belonged to this special category, but the leading authorities upon the subject of fevers do not to-day acquiesce in his theories.

Although it was as medical officer to Rugby School that Dukes substantially led his life, he took considerable part in public affairs. He was for years on the staff of the St. Cross Hospital, Rugby, was surgeon-colonel V.D. Midland Brigade and 2nd V.B. Royal Warwickshire Regiments, a medical referee under the Workmen's Compensation Act and the Mental Deficiency Act, and a justice of the peace for Warwickshire. He was twice married, first to Alice Mary Harford, who died very shortly afterwards, and secondly to Florence Emma, daughter of Mr. J. W. Battley, of Enfield, and had five sons and four daughters. We join with these, and with Dr. Dukes's many professional and personal friends, in regret at the death of a distinguished medical worker and pioneer.

LILLIAS HAMILTON, M.D. BRUX.,
L.R.C.P. & S. EDIN.

Lillias Hamilton, who died recently at Nice, was, when at school at Cheltenham, stimulated by Miss Beale to adopt some profession. She trained first as a nurse at the Liverpool Infirmary and later as a doctor at the London School of Medicine for Women and the University of Edinburgh, qualifying L.R.C.P. & S. Edin. and M.D. Brux. in 1890. The story of her life shows her to have had an enterprising and adventurous spirit. To those who knew her even slightly her energy and strength of purpose were apparent, while even in her books, especially in "The Vizier's Daughter," these qualities manifest themselves. Indeed, any girl who qualified in medicine 35 years ago, having previously submitted to the rigorous discipline of a hospital nurse's training, must have had a will of no common order. She might well have emerged from these strenuous years of preparation with the spirit of adventure somewhat dimmed, but Dr. Hamilton evidently took work easily in her stride as a preliminary to a life's career which proved as full of colour as even a school-girl's imagination could have painted it. From private practice in Calcutta, and the charge of the Dufferin Hospital there, she became court physician to the State of Afghanistan and established at Kabul a hospital whence at least some of the Western views on hygiene and the care of the sick spread to the surrounding population. She lost her own health in India while promoting that of others, and returned to this country in 1898, when, after a period of private practice, she became warden of the Studley Horticultural and Agricultural College for Women. During the war she returned to

medicine as officer in charge of a hospital in Montenegro, afterwards resuming her task at Studley of training women students to follow expertly yet another of the professions.

She will be remembered as one of the outstanding women of a transition period.

PHILIP PREBBLE, M.B., C.M. ABERD.

THE sudden death of Philip Prebble on Jan. 10th at his residence in Blackburn at the age of 59 removes one of the most respected practitioners of the town. Dr. Prebble was a native of Blackburn and received his early education there. He studied medicine at the University of Aberdeen, graduating M.B. and C.M. in 1895. He took post-graduate courses at Manchester, New York, and at various continental clinics before settling in Blackburn. He was appointed assistant physician to the Blackburn and East Lancashire Royal Infirmary in 1905, and at the time of his death was the senior physician at this institution. A life member of the Pathological Society of Manchester, he was also a former president and treasurer of the Blackburn District Medical Society, and a member of the Manchester Medical Society. He was at one time chairman of the Blackburn division of the British Medical Association, medical officer for the Blackburn Union Cottage Homes, and district medical officer for the Blackburn Union. Dr. Prebble was one of the few local medical practitioners who did not apply to be placed on the panel under the National Insurance Act. Later, he was elected a member of the Medical Service Subcommittee and chairman of the Pharmaceutical Subcommittee, and vice-chairman of the Finance and General Purposes Committee. He was for a few years a member of the Municipal Council.

Public Health Services.

HOSPITAL NOTES.

SCOTTISH HOSPITAL INQUIRY.

THE inquiry opened recently in Edinburgh into hospital needs in Scotland is of vital public importance. The Committee was appointed last June by the late Government to inquire into and report upon the extent and nature of the inadequacy of the present hospital and auxiliary services in Scotland and to make recommendations for the development and maintenance of those services to meet the needs of the community. The chairman, Lord Mackenzie, in opening the inquiry, stated that the remit was wider than the similar inquiry held in England, as it covered, in addition to voluntary hospitals, public health and Poor-law hospitals.

Evidence was opened by Mr. A. E. Maylard speaking for the city of Glasgow, who said that the present provision was not meeting the demand; this might be measured by the long waiting lists and the difficulty experienced by practitioners in getting patients into hospital. Prof. G. L. Gulland, speaking for Edinburgh, said accommodation was inadequate, and pointed out that the demands made upon voluntary hospitals by the community are in the future likely to increase owing to the ever-rising standard of diagnosis; further accommodation was even needed for acute illness. He suggested that auxiliary hospitals attached to the central hospitals should be provided, to which patients might be transferred after a shorter stay in the general hospital.

Sir David Wallace urged the utilisation of Poor-law hospitals to relieve the congestion; there was a great objection, due to the stigma of pauperism, on the part of many patients to entering these institutions; if this could be removed and the hospitals well staffed, there was no reason why they should not gain a reputation for good work and, moreover, patients would enter them unhesitatingly. The fact that

¹ THE LANCET, 1900, ii., pp. 89, 114, 289, 1384.

increase in hospital beds for patients must mean increased accommodation for the nursing staff had been lost sight of in the past, with the consequence that nurses were often "more or less stowed away" instead of being well housed and cared for. He was convinced that philanthropists were unlikely to support a State hospital, and this opinion was generally accepted.

Regarding maternity needs, Prof. B. P. Watson alluded to his experience in Toronto, where for many years he held a post in a maternity hospital of 600 beds of which about 150 were for private patients. All patients in this hospital paid for their maintenance; if they could not pay for themselves the municipality paid for them. There was no Poor-law in Canada; the private patients were accommodated in a separate block for which extra payment had to be made, and doctors were paid fees by patients in the private block. In Scotland, he said, there was urgent need for hospital accommodation for maternity cases; centres should be established in the larger towns where expert obstetricians were available.

Prof. T. K. Munro (Chair of the Practice of Medicine, Glasgow University) spoke of the inadequacy of the accommodation for surgical and tuberculous cases. He was opposed to the idea of voluntary hospitals taking paying patients. He would leave the Poor-law hospitals as they are, but thought that State contributions to capital expenditure might be accepted without detriment to the voluntary principle.

The inquiry is still proceeding and evidence is to be taken from well-known practitioners. The general consensus of opinion appears to be that the maintenance of the present voluntary system is desirable, but that increased accommodation is an urgent necessity; this might be achieved most easily by the institution of inexpensive auxiliary hospitals somewhat of the nature of convalescent hospitals. Some method of coördination between the various areas might be helpful. It was generally accepted that State control, or at least State aid, would be undesirable.

MEDALS FOR NURSES AT SHEFFIELD.—The committee of Sheffield Royal Infirmary has decided to award annually a gold, a silver, and a bronze medal to nurses for good ward work, general conduct, and examination results. Each year three nurses will receive four months' midwifery training at the Jessop Hospital. A large house close to the Royal Infirmary has been acquired to augment the accommodation for the nurses, who have been increased in strength in consequence of the growth of the number of beds, which now exceeds 500.

NOTTINGHAM CRIPPLES' GUILD.—The Duchess of Portland has laid the foundation-stone of a preventive, after-care, and training centre which is being built by the Nottingham Cripples' Guild at a cost of £7000. It is intended to deal with potential cripples, with children returning from special hospitals, and with those for whom vocational training can be provided. During the last six months there have been 4000 attendances at the present inadequate premises, and Mr. S. A. S. Malkin, the orthopaedic surgeon at the clinic, stated that there is a very definite cripples' problem in Nottingham.

KING EDWARD VII. HOSPITAL, WINDSOR.—The recent opening of the new nurses' hostel has enabled the setting aside of ten separate rooms as a paying ward. The ward is equipped with a special staff of nurses and is separate from the other portion of the hospital, but participates in all its advantages.

HOSPITAL SATURDAY FUND.—The income in 1924 exceeded that of 1923 (£100,765) by over £6000. The business house, workshop, and factory collections amounted to £79,583.

A FRIENDLY SOCIETIES' COLLECTING SCHEME.—The first year's working of a collecting scheme initiated by the local friendly societies in aid of the Bath Royal

United Hospital has produced £4900; 50 per cent. more was collected in the fourth quarter than in the first. The hospital serves a population of approximately a quarter of a million, and its area extends roughly from Swindon in North Wiltshire to Shepton Mallet in North-East Somerset, but the scheme has so far covered only about one-half of this wide district. Interest in the movement has been noticeably stimulated by the organisation of visits to the hospital by stewards of districts, collectors, contributors, and the general public.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED JAN. 10TH, 1925.

Notifications.—The following cases of infectious disease were notified during the week, namely:—small-pox, 91; scarlet fever, 1738; diphtheria, 1047; enteric fever, 49; pneumonia, 1292; puerperal fever, 49; cerebro-spinal fever, 12; acute poliomyelitis, 5; acute polio-encephalitis, 2; encephalitis lethargica, 45; dysentery, 3; ophthalmia neonatorum, 99. There were no cases of cholera, plague, or typhus fever notified during the week.

The cases of small-pox were reported from the several counties, as follows: Chester 2 (Dukinfield); Derby 12 (Derby C.B. 4, Bolsover 1, Chesterfield 3, Chesterfield R.D. 3, Shardlow R.D. 1); Lancaster 1 (Ashton-under-Lyne); Lincoln Holland 1 (Boston R.D.); Lincoln Lindsey 4 (Gainsborough); Northumberland 17 (Ashington 1, Weet-slade 11, Morpeth R.D. 5); Notts 23 (Hucknall 10, Kirby-in-Ashfield 11, Skegby R.D. 2); Warwick 7 (Coventry C.B. 1, Nuneaton 4, Atherstone R.D. 2); Yorks North Riding 22 (Middlesbrough C.B.); Yorks West Riding 2 (Bradford C.B. 1, Wortley R.D. 1).

Deaths.—In the aggregate of great towns, including London, there were 7 deaths from enteric fever, none from small-pox, 23 from scarlet fever, 47 from diphtheria, 79 from measles, 124 from influenza (as compared with 100 and 83 in the two preceding weeks). In London itself the deaths from diphtheria numbered 9 and from whooping-cough 18.

Medical News.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—The second of the present series of lectures will be delivered by Sir Humphry Rolleston on the Medical Aspects of Gall-stones on Jan. 30th, at 1, Wimpole-street, W., at 5.30 p.m. A combined course in Diseases of Children, arranged by the Paddington Green Hospital, Victoria Hospital, and the Children's Clinic, will begin on Feb. 2nd. There will be two sessions daily at 10 and 2 during the three weeks of the course. A four weeks' course starting on Feb. 2nd will be held at St. John's Hospital for Diseases of the Skin. A comprehensive course at the London Lock Hospital runs from Feb. 2nd until the 26th; early application for this course is desirable. Eight clinical demonstrations on Tropical Diseases will be given twice a week at the School of Tropical Medicine by Dr. G. Low and Dr. P. Manson-Bahr from Feb. 3rd. The course in Gynaecology at the Chelsea Hospital for Women, due to begin on Feb. 2nd, has been postponed until March 16th. From Feb. 16th to 28th the North-East London Post-Graduate College (Prince of Wales's General Hospital, Tottenham, N.) is holding an intensive course. The programme will cover the whole day, and will include all the general and special departments of the hospital, in addition to a special lecture each day at 4.30 p.m., free to members of the Fellowship of Medicine. The lecturers will be Mr. James Sherren, Dr. H. W. Barber, Dr. P. Manson-Bahr, and Mr. H. D. Gillies, as well as members of the permanent teaching staff. On the Saturday mornings there will be demonstrations of cases at associated hospitals: on the Early Diagnosis of the Infectious Fevers at the North-Eastern Fever Hospital, by Dr. Frederic Thomson; and on Mental Diseases at the L.C.C. Mental Hospital, New Southgate, N., by Dr. S. J. Gilfillan. The names of those wishing to attend this course should be sent to the Secretary of the Fellowship of Medicine, or to the Dean, Dr. A. J. Whiting, at 19A, Cavendish-square, W. 1, not later than Feb. 13th. Apart from the foregoing special courses, the general work, as indicated in the Fellowship *Bulletin*, is available and can be begun at any time. Copies of the syllabus of the above-mentioned courses and the *Bulletin* may be obtained on application to the Secretary at 1, Wimpole-street, W. 1.

MOORFIELDS RESEARCH SCHOLARSHIP.—A scholarship of the value of £50 per annum, tenable for one year, but renewable for a second year, is being offered at the Royal London Ophthalmic Hospital. The scholar will be required to give three mornings a week to research at the hospital on subjects approved by the Medical Board. Applications should be sent to the hon. secretary, Medical Board, Moorfields Eye Hospital, City-road, London, E.C.1, not later than Jan. 31st, if possible with suggested subjects of research.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—At the monthly meeting of the Faculty, held on Jan. 12th, the following were admitted as Honorary Fellows: Sir Humphry D. Rolleston, Bart., K.C.B., President of the Royal College of Physicians, London; Sir Archibald E. Garrod, K.C.M.G., F.R.S., Regius Professor of Medicine in the University of Oxford; and Lieut.-Colonel Sir Leonard Rogers, C.I.E., F.R.S., formerly of the Indian Medical Service and Professor of Pathology in the Medical College, Calcutta. Mr. Tom John Honeyman, M.B., Ch.B. Glasg., was admitted (after examination) as a Fellow of the Faculty.

MANCHESTER AND A CANCER COMMITTEE.—The Manchester Public Health Committee have agreed to coöperate in the work of forming a local cancer committee. Dr. R. Veitch Clark, the medical officer of health, last summer privately invited a number of medical men and others interested in the subject to meet and discuss the position. After several meetings of this unofficial committee it has now been arranged that a local cancer committee be established with representatives of the local hospitals, the University, the corporation, medical men, and others concerned. The Public Health Committee will be officially represented and take part in the proceedings. The new committee will consider the medical, industrial, and geographical aspects of the subject.

ALL-RUSSIAN CONGRESS ON MALARIA.—The Third All-Russian Congress on Malaria will be held in Moscow from Feb. 3rd to 8th. The Congress will discuss the epidemiology of malaria, the fight against malaria in Russia, and a number of scientific questions. Among those invited to the Congress are representatives of the Commissariat of Public Health of regional, provincial, and border districts of Russia; representatives of the malaria centres, of the health resorts and watering places, and of the war sanitary districts; as well as the representatives of the Central Committee of the Professional Union and the Central Board of the Social Insurance Service, of the medical societies, and of all the medical organisations of the Soviet Republics. All inquiries are to be directed to the Sanitary Epidemiological Department, Narkomsdrav Moscow, Maly Tcherkassky Pereulok, Moscow.

ROYAL COMMISSION ON NATIONAL HEALTH INSURANCE.—The thirteenth meeting of the Commission was held at the Home Office, Whitehall, on Jan. 15th, Lord Lawrence of Kingsgate in the chair. Mr. Joseph Cave, High Chief Ruler of the Independent Order of Rechabites, and Mr. Jonas P. Illingworth, a director of that Order, were examined on the following subjects: The rates of cash benefits, the deposit contributors' scheme, the administration charges, and the extension of medical benefit. Thereafter evidence was heard on behalf of the Rational Association Friendly Society, represented by Mr. Jonathan Duncan, general secretary, and Mr. Harry Bailey, assistant secretary. Questions as to the age limits for insurance, the size of societies, extension of benefits, workmen's compensation, and dental benefit were dealt with.

JUBILEE OF THE ROYAL SANITARY INSTITUTE.—This Institute came into being in 1876 for the purpose of aiding the carrying out of the provisions of the general Public Health Act of the previous year. It arranged congresses and meetings for the discussion of problems and procedure, exhibitions for showing sanitary appliances and encouraging their development, and training and examinations for sanitary officers. This work has been actively continued and developed for a period of 50 years, and the operations of the Institute have been extended throughout the United Kingdom and also to the overseas dominions of the Empire. By these means the Institute has taken a large part in educating the people in public health and in qualifying men and women to undertake official duty, thus rendering easier and more effective the work of public authorities in carrying out their health measures. It has been decided to celebrate the occasion of the jubilee of the Institute in 1926 by holding a congress in London, and it is hoped to make it an opportunity for gathering together those engaged in public health work from all parts of the Empire and for bringing responsible opinion to bear on the many questions affecting the health of the people.

Four free lectures on the Bodily Senses and their Mental Representation will be delivered by Sir Robert Armstrong-Jones, at Gresham College, Basinghall-street, London, E.C., on Jan. 27th, 28th, 29th, and 30th, at 6 p.m.

NAVAL MEDICAL COMPASSIONATE FUND.—At the quarterly meeting of the directors of this fund, held on Jan. 20th, Surgeon Vice-Admiral Joseph Chambers being in the chair, the sum of £60 was distributed among the several applicants.

ROYAL INSTITUTE OF PUBLIC HEALTH.—The Harben lectures will be delivered in the Lecture Theatre of the Institute at 37, Russell-square, London, W.C., by Prof. E. L. Collis on Phthisis and Industrialism (National and Occupational) with Reference to Other Infectious Diseases, at 4.30 p.m., on Jan. 26th, 27th, and 28th. Admission is free.

NORTH-WESTERN TUBERCULOSIS SOCIETY.—A meeting will be held on Jan. 29th, at 3.15 p.m., at the Public Health Laboratories, York-place, Manchester, when Prof. W. W. C. Topley will read a paper on Some Problems of Infection and Resistance in Tuberculosis in the Light of Recent Research. All medical practitioners interested are invited to attend.

THE LATE DR. JOHN FRASER.—The death is recorded at the age of 80 of Dr. John Fraser, who was a Commissioner in Lunacy for Scotland from 1895-1910, following on a period of seven years as Deputy Commissioner. Dr. Fraser graduated M.B., C.M. Edin., with first-class honours in 1870, and became F.R.C.P. Edin. in 1895. He was a keen botanist, and was a Fellow of the Royal Society of Edinburgh.

Dr. J. C. Spence, Dr. C. Worster-Drought, Dr. E. Mapother, and others.

Wednesday, Jan. 28th.

COMPARATIVE MEDICINE: at 5 p.m.

Discussion on

Canine Jaundice, with Special Reference to Leptospiiral Infection (with epidiascopic illustrations), to be opened by Dr. C. C. Okell, Mr. T. Dalling, and Mr. L. P. Pugh.

Thursday, Jan. 29th.

UROLOGY: at 8.30 p.m.

Discussion:

Radiotherapy and Electrotherapy in Diseases of the Bladder and Prostate.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

Monday, Jan. 26th.—8.30 p.m., Prof. A. Castellani: Parenteric Fevers.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn-fields, W.C.

Monday, Jan. 26th.—5 p.m., Sir Arthur Keith: Recent Discoveries of Fossil Man. (Hunterian Lecture IV.)

Wednesday.—5 p.m., Lecture V.

Friday.—5 p.m., Lecture VI.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.

Monday, Jan. 26th, to Saturday, Jan. 31st.—WEST

LECTURE HALL, Royal Society of Medicine, 1, Wimpole-street, W. Lecture arranged by the Fellowship of Medicine, and open to all members of the profession. At 5.30 p.m. Friday, Jan. 30th, Sir Humphry Rolleston, Bt.: The Medical Aspect of Gall-stones.—WEST END HOSPITAL FOR NERVOUS DISEASE, 73, Welbeck-street, W. Intensive course in the Diagnosis and Treatment of Common Diseases of the Nervous System. Daily, at 5 p.m., Lectures, including clinical demonstrations upon selected cases.—BETHLEM ROYAL HOSPITAL, St. George's Fields, S.E. Tuesday and Saturday, at 11 a.m., Lecture-Demonstrations by Dr. Porter Phillips and Dr. Thomas Beaton.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, Jan. 26th.—12 noon, Mr. Simmonds: Applied Anatomy. 2 P.M., Dr. Scott Pinchin: Medical Out-patients. 2 P.M., Mr. Bishop Harman: Eye Dept.

TUESDAY.—11 A.M., Dr. Endeau: Venereal Diseases. 12 noon, Dr. Burrell: Chest Cases. 2.30 P.M., Mr. Tytrel Gray: Surgical Wards.

WEDNESDAY.—12.15 P.M., Dr. Burnford: Medical Pathology. 2 P.M., Dr. Owen: Medical Out-patients. 2.30 P.M., Mr. Donald Armour: Surgical Wards.

THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Dept. 12 noon, Mr. Sinclair: Surgical Dyspepsia. 2 P.M., Mr. MacDonald: Genito-Urinary Dept.

FRIDAY.—10.30 A.M., Dr. Pritchard: Medical Wards. 10 A.M., Sir Henry Simson: Gynaecological Operations. 2 P.M., Mr. Vlasto: Throat, Nose, and Ear Dept.

SATURDAY.—9.30 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10 A.M., Mr. Banks-Davis: Operations on Throat, Nose, and Ear.

Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

TUESDAY, Jan. 27th.—4.30 P.M., Mr. N. B. B. Fleming: Eye Changes as Signs of Organic Disease.

FRIDAY.—4.30 P.M., Dr. C. E. Sundell: Enuresis.

Daily: In- and Out-patient Cliniques, Operations, Cliniques in Special Departments, &c.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, Jan. 29th.—4 P.M., Dr. Harrison: Routine Clinical Examination of the Urine.

ROYAL DENTAL HOSPITAL OF LONDON POST-GRADUATE LECTURES.

FRIDAY, Jan. 30th.—5 P.M., Mr. D. P. Gabell: Partial Dentures.

ST. JOHN'S HOSPITAL, 49, Leicester-square, W.C.

TUESDAY, Jan. 27th.—5 P.M., Dr. A. M. H. Gray: Xanthoma; Herpes.

THURSDAY.—5 P.M., Dr. J. M. H. MacLeod: Pemphigus and Allied Eruptions.

ST. ANDREWS INSTITUTE FOR CLINICAL RESEARCH.

TUESDAY, Jan. 27th.—4 P.M., Prof. A. Patrick: Clinical Application of Tests for Renal Efficiency. Discussion to be opened by Dr. Orr and Dr. Hynd.

SATURDAY.—A meeting of the Association for Clinical Investigation will be held in Edinburgh. The morning session will be in Prof. Murray Lyon's Wards in the Royal Infirmary at 11 A.M. An afternoon session will be held, the subject and time of meeting being announced at the morning meeting.

UNIVERSITY OF LIVERPOOL POST-GRADUATE LECTURES.

(At 3.30 P.M.)

MONDAY, Jan. 26th.—(At the Children's Hospital.) Mr. McMurray: Paralysis.

TUESDAY.—(At the Southern Hospital.) Mr. O. H. Williams: Colitis.

WEDNESDAY.—(At the Northern Hospital.) Dr. Murray Bligh: Broncho-pneumonia.

FRIDAY.—(At the Royal Infirmary.) Mr. Hallam: Dental Disease in Relation to General Medicine.

Appointments.

COHEN, J., M.R.C.S., L.R.C.P. Lond., has been appointed Medical Officer, Paddington Casual Wards, Metropolitan Asylums Board.

MITCHELL, A. PHILP, M.D., M.Ch., F.R.C.S. Edin., Assistant Surgeon to Leith Hospital.

Certifying Surgeons under the Factory and Workshop Acts: DUNCAN, C., M.B. Durh. (Chester-le-Street); MACINTOSH, J. F., M.B., Ch.B. Aberd. (Braemar); WIGAN, C. A., L.R.C.P. Lond., M.R.C.S. (Portishead); GERRARD, R. F., L.R.C.P. Lond., M.R.C.S. (Ellesmere); ROBEY, W. C. T., L.R.C.P., L.R.C.S.I. (Eastwood, Notts); HOLMES, A. M., M.B., Ch.B. Edin. (Heanor, Derby); PATON, W. R., M.B., C.M. Glasg. (Ilkeston).

Vacancies.

For further information refer to the advertisement columns.

Blackburn County Borough.—M.O.H. and Sch. M.O. £1000.

Cardiff City.—Asst. M.O. £600.

Central London Throat, Nose, and Ear Hospital, Gray's Inn-road, W.C.—Second Res. H.S. £75.

City of London Hospital for Diseases of the Heart and Lungs, Victoria Park, E.—H.P. at rate of £125.

Gloucester, Gloucestershire Royal Infirmary, &c.—Asst. H.S. £150.

Grocers' Company, Grocers' Hall, E.C.—Research Scholarships. £300.

Hospital for Sick Children, Great Ormond-street, W.C.—Cas. O. £400.

Huddersfield Royal Infirmary.—Sen. H.S. £225.

Hull Infectious Diseases Hospitals.—Res. M.O. £400 plus bonus.

Hull Royal Infirmary.—H.P. £200.

L.C.C.—Jun. Asst. M.O. Mental Hospitals. £432.

London Hospital, Whitechapel, E.—Obstet. and Gynaecological Reg. and Tutor. £400.

London Temperance Hospital, Hampstead-road, N.W.—Med. Reg. 40 guineas. Anaesthetist.

Maidstone, Kent County Ophthalmic Hospital for Diseases of the Eye, Ear, Nose, and Throat.—Hon. Rad.

Manchester, Ancoats Hospital.—Two H.S.'s. First 6 months at £100. Second 6 months at £150.

Manchester, Baguley Sanatorium.—Two Asst. M.O.'s. Each £350.

Margate, Royal Sea Bathing Hospital for Surgical Tuberculosis.—H.S.'s at rate of £200.

Mount Vernon Hospital, Northwood, Middlesex.—Jun. Asst. M.O. £75.

Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—Asst. Cas. H.S. at rate of £100.

Royal London Ophthalmic Hospital, City-road, E.C.—Four Refraction Assts. at rate of £100 each. Research Scholarship. £50.

Ryde, Royal Isle of Wight County Hospital.—Res. H.S. at rate of £180.

St. Mark's Hospital for Cancer, Fistula, &c., City-road, E.C.—H.S. £200.

St. Mary's Hospital, W.—Asst. Pathologist. £500. Cas. H.S. at rate of £100.

Samaritan Free Hospital for Women, Marylebone-road, N.W.—H.S. at rate of £100.

Seamen's Hospital Soc., Dreadnought Hospital, Greenwich.—P.

Seamen's Hospital Soc., Hospital for Tropical Diseases, Endsleigh Gardens, N.W.—Med. Supt. £250.

South London Hospital for Women, South Side, Clapham Common, S.W.—Clin. Assts.

Staffordshire Education Committee.—Asst. Sch. Med. Insp. £600.

Ventnor, Isle of Wight, Royal National Hospital for Consumption and Diseases of the Chest.—Second Res. M.O. at rate of £250.

Wakefield, Middleton-in-Wharfedale Sanatorium, near Ilkley.—Asst. M.O. £500.

West London Hospital, Hammersmith-road, W.—Hon. Surg. Reg. £100.

Willesden General Hospital, Harlesden-road, N.W.—Hon. Anaesthetist, &c.

The Chief Inspector of Factories, Home Office, London, S.W., announces the following vacant appointments: Highbridge, Somerset; Fricockheim, Forfar; and Stillington, Durham.

The Secretary of State for the Home Department gives notice of a vacancy for a Medical Referee under the Workmen's Compensation Act, 1906, for Dundee District (Sheriffdom of Forfar). Applications should reach the Private Secretary, Scottish Office, not later than Feb. 9th.

Births, Marriages, and Deaths.

BIRTHS.

ATKINSON.—On Jan. 10th, at Stainer-street, St. Thomas's-street, S.E., the wife of Dr. C. Hewitt Atkinson, of a daughter.

CADE.—On Jan. 15th, at Harley-street, W., the wife of Stanford Cade, F.R.C.S., of a daughter.

MARRIAGES.

CHURCHER—LANCASTER.—On Jan. 13th, at Christ Church, Westminster, Duncan Gillard Churcher, M.D., F.R.C.S., of Tarporley, Cheshire, to Nancy Thursfield Lancaster, M.R.C.S., L.R.C.P.

FELLOWS—GRIFFITHS.—On Jan. 13th, at Berhampore, Ganjam, India, Rev. B. F. W. Fellows, B.A., Baptist Missionary Society, Balangir, Orissa, India, son of late Mr. G. W. Fellows and Mrs. Fellows, London, to Alice Muriel Griffiths, M.D., B.S., Baptist Mission Hospital, Berhampore, younger daughter of Mr. and Mrs. T. L. Griffiths, of 27, Richmond-road, Cardiff. (Cabled.)

GLEN—DIXON.—On Jan. 17th, at St. Cuthbert's Church, London, S.W., Archibald Glen, L.R.C.P., M.R.C.S., to Enid Marcella Dixon, L.R.C.P., M.R.C.S.

WALKER—NICOL.—On Jan. 14th, William Wood Walker, M.B., to Rosabel, youngest daughter of Mr. and Mrs. George C. Nicol, Sarre-road, N.W.

DEATHS.

DINGLEY.—On Jan. 16th, at "St. Norberts," Sutton, Allen Dingley, F.R.C.S., aged 68 years.

DUKE.—On Jan. 17th, Maurice Smelt Duke, M.R.C.S., L.S.A., late of Kennington Park-road, aged 73.

IRVINE.—On Jan. 14th, at Westminster Hospital, the result of an accident, Lieut.-Colonel Lewis Irvine, late R.A.M.C., of Whitehall Court, S.W.

MACMUNN.—On Jan. 12th, at a nursing home in London, James MacMunn, M.D., F.R.C.S., Easkey, Co. Sligo, aged 69 years.

SHURLOCK.—On Jan. 16th, at a nursing home, Arthur George Shurlock, M.A., M.B., B.Ch., D.P.H. Camb., M.R.C.S., L.R.C.P., of Lime-avenue, Derby, and recently of Brockenhurst, Hants, aged 30.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

TOBACCO, HEALTH, AND EFFICIENCY.

A Statistical Inquiry into the Physiological Effects of Smoking Tobacco, Conducted at Antioch College, Yellow Springs, Ohio, U.S.A.

BY J. ROSSLYN EARP, M.A. CAMB., M.R.C.S. ENG.

ONE of the most sustained indictments of tobacco—sustained, that is, by number of witnesses rather than by weight of evidence—is that it injures the wind. So commonly is this believed to be true that athletic coaches the world over will prohibit use of tobacco to their teams in training. If breathlessness is really increased by the use of tobacco this must be due to poisoning either of the respiratory machinery or of the nerves or muscles of the heart or of the oxygen-carrying materials of the blood-stream itself. In the following study, endeavour has been made to evaluate by quantitative methods the actual effect on the function and efficiency of the cardiac and respiratory organs of slight, moderate, or heavy use of tobacco. No observations have been made on the effect of smoking on the chemistry of the blood.

Division of smokers into light, moderate, and heavy groups must obviously be made by arbitrary methods and can be only approximately correct. No account can be taken of the possible variations in toxicity of different brands of tobacco or in the wide variations in the size of pipes and the completeness of combustion. For the purpose of this study a man was considered to be a light smoker if he used two cigarettes, one pipe, or one cigar or less per day, a moderate smoker if he used up to ten cigarettes, three pipes, or two cigars a day, and a heavy smoker if he used more than this.

The material for this study is derived from the medical examination given to every Antioch student each year. For various reasons only records of the men are being used. The results are shown in Table A.

TABLE A.—Average for Group in—

Amount of tobacco used.	No. of cases.	1	2	3	4	5	6	7	8	9	10	11
		Stand- ing pulse- rate.	Lying pulse- rate.	Differ- ence between 1 and 2.	Pulse- rate after exer- cise.*	Differ- ence between 4 and 1.	Systolic blood pres., stand- ing.	Systolic blood pres. after exer- cise.*	Differ- ence between 7 and 6.	Diastolic blood pres., stand- ing.	Difference between 6 and 9 (pulse pressure).	Deviation from Dreyer V. C. Standard Class A.
		per minute.					millimetres.					litres.
Non-smoker . . .	172	79	69	11	120	47	120	143	23	84	38	0.154
Light smoker . . .	24	79	69	11	129	50	119	140	21	87	32	0.0809
Moderate smoker . .	38	80	67	13	126	47	112	135	24	84	31	0.186
Heavy smoker . . .	70	80	69	13	123	44	119	140	23	83	35	0.069

* Lifting the body weight through 2 feet ten times in 30 seconds or approximately 3000 foot pounds of work in 30 seconds.

It is obvious without any further statistical procedure that smoking in the degree to which it is carried on by Antioch students does not materially affect the functional efficiency of the cardio-vascular system, or capacity of the lungs as measured by stated tests. It must, however, be emphasised that these tests are not all-inclusive. It may be that the coordination between the cardio-vascular and the respiratory system is less efficient in smokers than in non-smokers, or that the oxygen affinity of the blood is materially lowered in smokers by combination of carbon monoxide with the hæmoglobin. I hope later to make some research in this regard.

In the meantime Table B is a rough indication that the prejudice of the athletic coach against smoking has some justification from experience. As will be seen from Table A, there are actually more non-smokers than smokers in the college in the proportion of 172 to 132. Since the track meet was open to all comers the prizes should have gone to non-smokers in this same proportion had habitual smoking no effect on athletic ability. It will be seen that the actual distribution of prizes was overwhelmingly in favour of the non-smokers.

TABLE B.—Showing Distribution of Non-smokers, Light, Moderate, and Heavy Smokers in Winners of Intramural Track Meet, May, 1924.

Event.	First place.	Second place.	Third place.
100 yards dash . . .	H	N	—
Shot put . . .	M	N	(H) ?
220 yards dash . . .	N	N	—
Pole vault . . .	N	N	—
Javelin throw . . .	N	L	—
Half-mile run . . .	N	N	N
440 yards run . . .	N	—	—
High jump . . .	L	N	N
1 mile run . . .	N	N	N
Broad jump . . .	L	N	N
Discus throw . . .	N	(N) ?	N
Relay team . . .	N	N	L

N = Non-smokers. L = Light smokers.
M = Moderate smokers. H = Heavy smokers.

An incidental, but very striking observation is the negative correlation shown between smoking and scholarship. Table C shows the average cumulative scholarship of the three groups

TABLE C.—Average Cumulative Scholarship.

Non-smokers . . .	4.03	Heavy smokers . . .	3.33
Light smokers . . .	3.62	All smokers . . .	3.45
Moderate smokers . .	3.39	All in this study . .	3.83
Probable error of difference, non-smokers and smokers			
Difference is . . .			
0.58 ± 0.08			

of smokers and of the non-smokers. For all smokers together this average works out at 3.45. Since the "probable error" of difference between the two groups "smokers" and "non-smokers" is only 0.08, whereas the observed difference is 0.58, the chances are about 500,000 to 1 against this difference being due to chance alone. A study of the psychological ratings of the two groups showed that there was no significant difference in intelligence, as measured by the Thurstone test. This observed difference in scholarship must, therefore, be due to one of two things: either the use

of tobacco reacts unfavourably in some way upon mental processes or else the type of mind to which smoking appeals is a type less given to mental application. It would be possible to decide between these two explanations only if the smokers could be persuaded to desist for a year or more from their habit. It is unlikely that they can be persuaded to do this as a body. Observation will be kept on the scholastic progress of those who do stop smoking for one reason or another.

Summary.

Of 304 men students at Antioch College, 172 are non-smokers, while 132 use tobacco in various amounts. Although the tests of the cardio-vascular system used in medical examinations do not indicate a superiority in the physique of non-smokers, the latter prove themselves the better athletes in practice, and show a significant advance in their record of scholarship.

I have to thank Mr. M. W. Richardson for the statistical calculations in relation to scholarship, and my assistant, Mr. Louis Harap, for the laborious detailed work involved in the compilation of the remaining tables.

POPULAR TUBERCULOSIS PUBLICATIONS.

A VERY welcome sign of the growing recognition of the value of propaganda in the campaign against tuberculosis is to be found in the increasing number of publications dealing with tuberculosis in a popular manner. We need only mention a couple of such periodicals. *Commonwealth* is issued by the Tuberculosis Committee of the Belfast Corporation in the interests of general health and the prevention of tuberculosis. The first number, which runs to eight pages, is an excellent example of a publication which aims at being educational as well as readable, and its editor, Dr. A. Trimble, has introduced so much variety into his menu, not omitting the lighter touch, that his work is sure to enjoy general appreciation. Another popular publication, which we hope deserves the term "periodical," is the *Christmas Magazine* of the Bridge of Weir Sanatorium. Like the average school magazine, it contains much that is of strictly local interest, but here and there words of wisdom, of value to every reader, are to be found. In both these publications established facts about tuberculosis are given prominence, whereas nothing is said to puff the latest "cure" or advertise some new sensational statement of doubtful veracity about tuberculosis.

THE QUACK ABROAD.

WITH all its century-old mystical medical lore, one might think that China would be proof against the vulgar wiles of upstart occidental quackery, but the reverse is the case. A Chinese contributor to the current number of *Hygeia*¹ has arranged an interesting little portrait gallery—of which we reproduce one masterpiece—of familiar Western nostrums in Chinese guise. Scientific medicine in China is trying to

九腎保製秘氏安兜
治主 驗弱症痛腎
無可起不弱
匹效矣即之
患一此治朕
者切允愈兆
盡病統較為
試症治重背
之效腎之腰

背痛 苦

An advertisement familiar to Chinese newspaper readers.

combat ignorance and disease, but there, as here, it must bear that old man of the sea—the quack—upon its shoulders. Mr. Chi-Chen Wang states that a survey of several issues of *Shun Pao*, the oldest and largest Chinese newspaper in Shanghai, reveals the startling fact that over one-third of its total advertising space is bought by patent medicine manufacturers or their agents. Some of the provincial papers derive practically all of their advertising revenue from nostrum vendors, for Chinese merchants as a whole have not yet learned to extend their business by advertising methods, and Chinese newspapers cannot afford to turn down space buyers. Patent medicine concerns, continues Mr. Wang, really introduced the art of advertising into China. With their striking illustrations and their striking claims they have lured many victims. Of late, since competition has become keener, the more enterprising have resorted to coupons and no-money-in-advance methods; others have gone so far as to offer free trial treatments. Mr. Wang points out rather ingenuously that the American public (and we presume he might include the British public) is familiar with such inducements and is wary about extravagant claims, but that to the Chinese public "such inducements seem true." There is, however, a reverse to the picture. An American writer to the *Dearborn Independent*, as quoted in a current issue of the *Bruxelles Médical*, states that there are about 2000 Chinese charlatans at present practising in the United States, under such titles as "oriental healer" and "herbalist." Their clientèle is composed

¹ Patent Medicine in China. By Chi-Chen Wang, *Hygeia*, Chicago, January, 1925.

entirely of white people, for, the writer remarks, "a Chinaman would never dream of committing himself to their tender mercies." These enterprising gentlemen work by means of "ingenious advertisements" in the newspapers, and the drugs they supply are certainly fascinating. For example, dried toads are prescribed for kidney diseases, while the hair of a lion or a tiger is claimed as a specific for heart troubles. Unfortunately, however, the origin of the latter medicament can usually be traced to a defunct cat or dog. Thus do East and West meet on the common territory of quackery.

TREATMENT OF LUMBAGO.

To the Editor of THE LANCET.

SIR,—I should like to know the opinion of other medical officers on the treatment of lumbago by subcutaneous injections in the buttocks of 2 gr. doses of sodium salicylate. In 20 cases I have so treated, the injections being given twice a week, there have been no further attacks.

I am, Sir, yours faithfully,

S. K. GANGULI, B.A., M.B.,
Lieut., I.M.S.

A CHARMING ROAD BOOK.

WE have received from the Dunlop Rubber Co. the first volume of a series of pictorial road plans entitled "On the Road," published by Ed. J. Burrow Co. Ltd., Cheltenham and London (price 6d.). This volume covers the highway between London and Brighton, Worthing, Eastbourne, Hastings, Folkestone, Dover, and Margate. A clear red road runs from the bottom to the top of each of 37 maps and on each side of it are delightful little sketches of taverns, cathedrals, bridges, fruit fields, and castles which abound in this corner of England. Regular sea-level figures show where the road-user will swoop down into a valley or skim over a hill top, and there are frequent notes and an introduction by Mr. Ed. J. Burrow, F.R.G.S.

A VERY SMALL COOLIDGE TUBE.

A PORTABLE X ray outfit recently developed in the research laboratory of the General Electric Company of America weighs only about 20 lb., and complete with its transformer and all other necessary parts occupies a box measuring 6½ by 10½ by 8½ inches. The tube operates at 56,000 volts (maximum) and 10 milliamperes, and is mounted in oil. The bulb, 1½ inches in diameter, is of glass, which contains 55 per cent. by weight of lead. The window from which the X rays emerge is of thin-walled, lead-free, lime glass. This is probably the smallest Coolidge tube on sale.

THE MEDICAL BUREAU OF LOURDES.

WRITING in the magazine of the Society of our Lady of Lourdes in December, 1924, Dr. Francis Izard criticises the views expressed by THE LANCET some four years ago on the cures reported to have been effected at Lourdes, when we implied that the cases which benefited from pilgrimages to the Shrine of our Lady were of the functional rather than the organic type. Dr. Izard claims that the work of the Medical Bureau of Lourdes is carried out with extreme care and earnestness with the object of establishing all cases of authentic cures, but we hold that a strict winnowing in the preliminary stages of the cases which come under treatment at Lourdes, the scrutiny being carried out by practitioners expert in neurological diagnosis, would materially alter the percentage of cures of organic disease achieved at the grotto.

A BOGUS DOCTOR.

MEDICAL men in London and the provinces have been victims to such an extent of late of a bogus doctor that Scotland Yard has issued a special warning to the profession. The man, who is well educated and of smart appearance, calls on doctors or Irish people of social position. He occasionally claims acquaintance with their relatives and friends living in Ireland, says he has obtained an appointment in Ireland, or for some other reason, has to cross to Ireland that evening, and has run short of cash. He asks for a loan of cash in exchange for a cheque on an Irish bank. He gives the name of Fitzgerald, Moore, Black, McCormack, O'Brien, or Murphy, and is about 40 or 45 years of age. The description of him available is: Height 5 ft. 10 in., dark hair streaked with grey, and brushed back; eyes grey or blue, clean shaven, good appearance and address. Dressed in grey lounge suit, light grey overcoat, and soft felt hat.

Clinical Lectures

ON

APPENDICITIS: ITS CAUSATION,
DIAGNOSIS, AND TREATMENT.

Delivered at the Bristol Royal Infirmary

By A. RENDLE SHORT, M.D., B.S., B.Sc. LOND.,
F.R.C.S. ENG.,SURGEON TO THE BRISTOL ROYAL INFIRMARY; LECTURER ON
PHYSIOLOGY IN THE UNIVERSITY OF BRISTOL.

PART I.

THE CAUSATION OF APPENDICITIS.

Rise in Frequency in Last Thirty Years.

At first sight the etiological problem would appear to be very simple. It is quite certain that the disease was uncommon in this country until somewhere about the year 1895, and that during the period 1895-1905 it rose to its present great frequency. As the writer has shown elsewhere,¹ the records of the Bristol Royal Infirmary prove conclusively not only that appendicitis was not diagnosed at all frequently before 1895, but that very few cases can have occurred. The physicians and surgeons of that period were on the look-out, for the notes often state, "No tenderness in the right iliac fossa." I have read carefully through all the notes, medical and surgical, for the years 1880, 1885, and 1890, and sought to force cases otherwise diagnosed into being cases of appendicitis, but only a few very dubious additional cases can be added to those actually recorded. Mr. Sherren² has shown that the rise at the London Hospital took place during the same period (Table I.).

TABLE I.—Cases of Appendicitis (Acute) at the
Bristol Royal Infirmary.

Year.	Probable or certain cases.	Additional very doubtful cases.	Total in-patients per year.	Year.	Probable or certain cases.	Additional very doubtful cases.	Total in-patients per year.
1880	4	2	2591	1910	58	—	4149
1885	2	1	3370	1915	75	—	3481
1890	4	6	2913	1917	98	—	3907
1895	15	—	2910	1918	113	—	4021
1900	23	—	2865	1923	162	—	6042
1905	64	—	3762				

Private practice shows the same scarcity. The late Dr. Shingleton Smith, who had one of the largest consulting medical practices in Bristol in the eighties and nineties, found very few cases of appendicitis among his records, as compared with other now less common abdominal diseases.

Appendicitis did not become returnable as a cause of death in the Registrar-General's statistics until the year 1901. Table II. gives the death-rate from appendicitis per million living for England and Wales:—

TABLE II.—Death-rate from Appendicitis per Million
Living for England and Wales.

Year.	Death-rate.	Year.	Death-rate.
1901	38	1911	75
1902	45	1913	68
1903	52	1915	67
1905	57	1918	72
1910	66	1920	67

At first the incidence of the disease was greater in towns and among males, but of late years there has been little difference. The case-mortality from appendicitis used to be much higher than now; in 1903, at St. Mary's Hospital, it was as high as 30 per cent.

¹ Rendle Short: Brit. Jour. Surgery, October, 1920, viii., 171 (with bibliography).

² Sherren: Practitioner, June, 1905.

It will further be observed that the privations of the war period did not alter the incidence of the disease.

It cannot be claimed, of course, that the number of operations for acute appendicitis at the Bristol Royal Infirmary is an entirely accurate register of the prevalence of the disease in the district, but that there was a big rise in the Bristol district between 1895 and 1910 is absolutely certain. In 1885 there were only three cases admitted, and they all recovered, without operation. In 1915 there were admitted 34 cases, from within the town itself, with a perforated appendix. Surely if there were a similar number of cases in the town in 1885, most of them would have been bound to seek admission to a hospital for nursing through such a severe illness. (The urban population rose from 206,503 in 1881 to 352,859 in 1915.)

Distribution of Appendicitis.

The distribution of the disease in the community brings out some points of importance. It is commonest between the ages of 10 and 30, but most fatal between 5 and 15. It is rare under 3. The oldest patient I have operated on was aged 84, and in spite of the fact that the appendix had perforated he did very well. There are families which appear to be particularly prone to the disease. During the war it seems to have been about equally common amongst soldiers and the general population. The most interesting feature, however, is the relative immunity of the inmates of such institutions as workhouses, homes for poor children, and prisons. For ten years there was only one case at Portland Prison. The writer is the surgeon usually called in for operations on the inmates of two local institutions; the one is a big public school where the boys are well fed on a modern diet, and the other is an orphan home. Although the children at the orphanage are more numerous, and are in residence all the year round, there were in a five-year period 19 cases of appendicitis at the school and only four at the orphan asylum. The difference seems to lie in the diet. At the orphanage the daily routine includes porridge and bread with margarine, dripping, or treacle, tinned meat with potatoes and greens on certain days, and fresh meat once a week, with broth or rice on the other days.

Turning to the national distribution, we find briefly that appendicitis is common in the more civilised European and American countries, rather uncommon in the more poverty-stricken countries of Southern Europe, and very rare in Asiatics, Africans, and Polynesians. If, however, individuals from these races are taken into the service or society of Europeans and eat their food, they acquire the European's liability to the disease. Indian students in this country are by no means immune. In the United States it is even commoner than here, but is seldom seen in the "black belt" of Alabama or in negro schools or institutions. A missionary from Barbados tells me that he has never heard of a case in a West Indian negro, but whites are frequently affected; the population is about 12 blacks to 1 white.

Now the characteristic difference between those peoples who do and who do not get appendicitis is that the food of the latter is much simpler, contains a larger relative bulk of coarse vegetables, and often a smaller amount of meat. In some countries where appendicitis is very rare the amount of meat eaten is considerable; for instance, in Abyssinia and in Madagascar. We have no accurate statistics of the incidence of the disease amongst populations that live very largely on meat, such as the Eskimos and Paraguayans, but as far as we know there is no great amount of appendicular trouble. A curious and interesting fact is that apes in captivity acquire the human liability to appendicitis (present in 10 out of 61 autopsies in chimpanzees).

When we come to piece together what we know about the distribution of the ailment, we shall readily conclude that it must be due to some food factor, but we shall need to tread warily in seeking to go further. So many baseless theories have been advanced that the late Dr. Charles Mercier, with characteristic playful

E

irony, maintained that the trouble is due to the abandonment of wig-wearing; there were no recorded cases from the days of Charles II., when wigs came in, till the end of the eighteenth century, when they went out, except on the heads of judges, barristers, and Victorian bishops. He knew of no cases in legal luminaries—"and who ever heard of appendicitis in a wigged bishop?"

Change in Dietetic Habits in Past Thirty Years.

Now, our significant period, 1895 to 1905, has been very important in the dietetic history of our country, because it has witnessed the passing of the older food habits of our people, and the inauguration of the modern dependence on imported articles. Up till 1895 England in the main fed herself; since that time she has paid other countries to feed her. This may be demonstrated by a study of the Blue-books relating to food imports. The principal cargoes are wheat and other grains, meat, butter, tea, coffee, cocoa, sugar, rice, bananas, oranges, currants, and raisins. Most of these may be dismissed the court with the briefest of inquiries.

There is, however, much to be said for the widely held view that meat-eating has led to an increase of the disease. Table III. shows the average annual consumption of imported beef and mutton from 1880 to 1917. Compare this with Table I., showing the number of cases of acute appendicitis at the Bristol Royal Infirmary. The correspondence is striking. O. T. Williams demonstrated that the inflamed appendicular mucosa may contain an excess of calcium soaps and other insoluble compounds of the saturated fatty acids, which he believes to have been derived from meat-fats.

TABLE III.—*Showing the Annual Consumption of Imported Meat per Head of Population, for United Kingdom, in Pounds.*

Year.	Bacon and ham.	Beef: salted, frozen, fresh.	Mutton: fresh, frozen, &c.	Beef from live cattle imported.	Mutton from live sheep imported.
1880	15.9	2.5*	—	5.8*	—
1890	13.5	6.0	4.9	11.1	0.6*
1895	14.6	6.7	7.5	8.1	1.3*
1900	19.5	11.7	9.2	9.2	0.6*
1905	17.4	13.1	9.9	9.5	0.26
1910	11.2	17.4	13.5	3.2	0
1914	14.2	18.0	12.4	0	0
1917	18.0	18.0*	6.0*	0	0

* Rough figures calculated from published returns.

As Table III. shows, the importation of beef doubled in the critical period 1895 to 1905. Imported mutton rose from a mere trifle in 1880 to 13.5 lb. per head in 1910. If this rise was the effective cause of the great increase in appendicitis which was coeval with it, the fault might lie in the preservation of the meat, or in the excessive quantity eaten.

Question of Preserved Meat.—Although the reasons for doubting the drawbacks of the preservation may not be quite conclusive, there are points which go to exonerate it. During the war the diet of the soldier and sailor, especially overseas, contained a much larger proportion of preserved meats than they were accustomed to in private life, as those of us who were in France can very well remember. Yet the incidence of appendicitis amongst the serving forces was certainly not excessive; perhaps less than in the civilian community. In institutions the meat is usually of the preserved variety, but appendix troubles are uncommon. In 1921 about 47 per cent. of the meat eaten was imported; if those numerous members of the community who always insist on having English meat were free from appendicitis, it would be a disease of the poor rather than of the well-to-do and the farming class. There is no evidence of any such class-immunity. Europeans in the tropics get very little frozen meat, yet they suffer.

Question of Increase in Total Meat-eating.—No doubt in the "hungry forties," and for many years after, meat was very seldom seen on the tables of the poor,

at any rate in towns. But it must be remembered that although many persons got very little meat prior to the advent of the meat-ship fleets, there has always been a considerable minority who got plenty. The farming fraternity, soldiers, and well-to-do families ate as much as they do to-day. Our old songs sing the praises of the "Roast Beef of Old England." There was a farmer's proverb in those days that a goose is a fool of a bird, too much for one and not enough for two. Returns to Parliament made in 1889 as to soldiers' meat rations and the meat eaten by carmen show that if meat-eating is the cause of appendicitis there ought to have been plenty of cases in 1889.

Then again, although there was such a rise in the import of meat, there was by no means such a conspicuous rise in its consumption, for the importation of live cattle and sheep for slaughter ceased, and the consumption per head of home-grown beef and mutton was falling (Table IV.).

TABLE IV.—*Showing Consumption per Head of All Imported Meats, Dead or Alive, in Pounds per Annum, also Resident Cattle and Sheep.*

Year.	Population of United Kingdom.	Resident cattle.	Resident sheep.	Consumption of all imported meats.
1885 ..	36,300,000	6,600,000	26,000,000	24.1
1890 ..	—	6,500,000	27,000,000	36.1
1895 ..	39,200,000	6,300,000	26,000,000	38.2
1900 ..	—	6,800,000	26,000,000	50.2
1905 ..	42,900,000	7,000,000	25,000,000	50.1
1910 ..	—	7,000,000	27,000,000	45.3
1914 ..	46,000,000	7,100,000	24,000,000	44.4
1917 ..	—	—	—	42.0

If we compare the rise in the incidence of appendicitis at the Bristol Royal Infirmary with the figures for the consumption per head of all forms of imported meat, dead or alive, there does not seem enough difference in the meat figures between 1895 and 1905 (and later years) to justify the theory that appendicitis is due to the increase in meat-eating. The actual figures are 38 lb. per head in 1895 and 44 lb. in 1914, and against this has to be set the rather smaller consumption of home-grown meat. And there are other difficulties in the theory. Severe meat-rationing during the war did not reduce appendicitis.

The Question of Food Preservatives.—We cannot well blame the use of boric acid, formalin, and other chemical food preservatives. They came into use too early (1880 to 1895). Since 1900 the use of antiseptics has declined, but the amount of appendicitis has greatly increased. In Denmark, where all antiseptics are prohibited in foods, the disease is common.

The Ultimate Cause of Appendicitis.

What, then, is the ultimate cause of appendicitis? Our apparently simple problem has become unexpectedly complicated, just when our wealth of data seemed about to yield up its secret. It is, of course, possible that a vitamin-defect may be responsible. But we ought not to blame the unknown before exhausting the possibilities of the known. One thing is quite certain and can be mathematically demonstrated, and that is that the older, coarser, cellulose-containing vegetables have suffered a relative elimination in our modern dietaries. When we consider that the citizen of to-day regales himself with 18 lb. of imported beef, 6 or 10 lb. of imported mutton, and an enormous quantity of imported wheat-flour, to say nothing of fruits, &c., none of which articles of diet from overseas were available for his fathers, it is clear that there has been a real increase of these food-substances in the diet of the people, and therefore a reduced proportion of the old-fashioned vegetables. We do not lose sight of the fact that when the population was smaller the British farmer could do more for his fellow-countryman in supplying him with meat and corn, but the disparity is too great to be explained entirely thus.

Summary.

Let us see how far this possible explanation will fit our facts. (1) The national distribution of appendicitis is in favour of the hypothesis. In practically all the lands where it is rare or unknown, the diet contains a large proportion of vegetables and cellulose-containing articles. If the natives desert their own food habits and take to European diet they get appendix troubles. (2) The time factor in this country is right. It was during the period 1895-1905 that England ceased to feed herself, and the modern rise of the disease coincides remarkably. (3) Institutions where the older and cheaper dietary prevails enjoy a relative immunity. (4) At first appendicitis was a disease of males and of the town. At first the breadwinner was given the best food; in the country, the home-grown produce maintained its place on the table for a while. Now there is little difference between the diet of town and country. (5) Apes in captivity are liable to appendicitis, and their cage diet no doubt contains more food of the break-and-milk variety and less coarse vegetables and roots than in the wild state.

There is some experimental evidence that deprivation of cellulose may lead to inflammation of the cæcum. Von Knierien showed in 1885 that rabbits fed on a cellulose-free diet developed inflammation of the cæcal region. In carnivores this did not occur. The effect seems to be partly mechanical, for horn-shavings will avert the trouble. It is well known, of course, that cellulose is not acted on by the ordinary digestive ferments.

Table V., from Bunge, gives the cellulose content of some foodstuffs.

TABLE V.—Percentage Cellulose Content of Some Foodstuffs.

Wheat flour .. 0.4	Spinach 8.1	Asparagus .. 17
Rice 0.7	Green peas .. 8.7	Cabbage 18
Wheat 2.9	Carrots 8.8	Strawberries .. 19
Potato 3.1	Apples 10	Melon 22
Lentils 4.1	Radish 12	Pears 25
Beans 4.1	Cauliflower .. 13	Raspberries .. 47
Onion 5.0	Cucumber .. 14	

THE DIAGNOSIS OF ACUTE APPENDICITIS.

A consecutive series of personal cases, including 400 operations for acute appendicitis and many others for interval cases and for appendicular gastralgia, all falling within a ten-year period, have been analysed for the purpose of these papers. (The records of a number of cases operated on whilst overseas on war service are not available.)

In the majority of cases there is no difficulty in making a diagnosis, but as every man of experience knows, it may be very hard to arrive at a correct opinion. One may be deceived, first, into thinking the case is not one of appendicitis when it is, or second, a diagnosis of appendicitis may be incorrectly made. Only such difficulties as the writer has actually encountered will be discussed.

It may be taken as a general rule that so long as the pulse and temperature, evening and morning, are normal, and the pain and tenderness in the abdomen not very marked, it does not matter seriously even if a genuine appendicitis is undiagnosed and let alone for a few days. The cases which one has seen in which the appendix has been allowed to perforate and become really dangerous, have all been due either to an abnormal position of the appendix or to the coincidence of diarrhoea.

Sources of Diagnostic Error.

Abnormal Position.—The most dangerous "miss," in my experience, is when the patient has an appendix lying deep in the pelvis. The error can only be avoided, first, by bearing it constantly in mind, and second, by making a rectal or vaginal examination in all doubtful cases. Zachary Cope's sign—pain and resistance on internal rotation of the thigh due to stretching of the obturator internus—may help in late but not often in early cases. Another error due to position, which I once made in consultation with a distinguished physician, arose from the inflammation occurring at the tip of a long retrocaecal appendix.

In this case we thought the duodenum was at fault, on account of the tenderness being so high up. The gall-bladder, too, may be wrongly suspected. Sometimes the signs may be far out in the loin.

Appendicitis accompanied by diarrhoea is very likely to give rise to difficulty in recognition. To know that it may occur is a considerable safeguard. One gets fever, pain, and tenderness, of course, with a simple diarrhoea, but the tenderness will not be *constant* in the appendix region. It is surprising sometimes how badly inflamed an appendix, even if normally situated, may become, and yet the physical signs in the way of tenderness and resistance be very slightly marked. It is wise to use as a working rule, that pain with vomiting and with fever, and even *slight* tenderness and resistance in the right iliac fossa, if these are constant, demand an exploration, unless some definite diagnosis besides appendicitis can be made.

Turning to the other class of error, every surgeon must confess that he has removed a certain number of appendices which did not deserve the suspicion cast upon them. The simple though unsatisfactory fact is that we badly need a reliable sign of early appendicitis. The various signs suggested are not very helpful in the really difficult type of case, and the same applies, in my experience, to Zachary Cope's signs, the obturator test already referred to, and the psos test—pain on over-extending the thigh.

The most frequent error, in my experience, has been the removal of the appendix when no abnormality whatever could be found in the abdomen and no evidence of disease ever came to light elsewhere. These cases may be very puzzling, and it may be impossible to discover on analysis afterwards any difference either in quality or degree between the signs and symptoms in one of them and in a case of badly inflamed appendix. I have been impressed by the fact that these pseudo-appendicitis cases are very uncommon in children under the age of 15. They are most often seen in women over 30. In cases of the colic and wind troubles so often met with in the course of an attack of influenza the careless diagnostician will fall into the trap. But under these circumstances *pain is not the first symptom*, as it almost invariably is in genuine appendicitis, and although there may be quite marked pain and tenderness in the right iliac fossa, they keep shifting about, one may feel wind rolling round, and an enema gives prompt and effectual relief.

Persons suffering from the condition shortly to be described under the title of "mobile cæcum," which is so confusing in the diagnosis of chronic appendicitis, may have a rise of temperature occasionally, from some totally disconnected cause, and this may lead to error.

Sometimes the operator has qualms as to his diagnosis when a careful examination of the interior of the appendix will show the true cause to have been the presence of oxyurides. On 15 occasions I have made a diagnosis of acute febrile appendicitis, and removed an organ apparently normal, but inspection showed that it contained threadworms. One will usually find the nearest lymphatic nodes swollen in these cases, and it seems beyond question that the pain, fever, and vomiting are due to the presence of the worms.

The next most frequent error in the series has been the failure to distinguish between appendicitis and *tuberculous mesenteric glands in children*. On three or four occasions within my memory the abdomen has been opened on a confident or tentative diagnosis of acute appendicitis, and nothing found but tuberculous glands, few or many, either in the mesentery, or retroperitoneal in the angle between the termination of the ileum and the cæcum. In one case the appendix was also slightly inflamed, probably not enough to give rise to a temperature, and the lymphatic glands in the area draining the appendix showed some swelling and redness superadded to an old-standing enlargement due to tuberculosis, in which many other mesenteric glands shared. This suggests that the cause of the fever and pain in other children with tuberculous mesenteric glands whose appendices are

normal, may be some absorption of toxins or bacteria from the bowel, which the damaged lymphatic nodes are unable to arrest without suffering. It is difficult at present to give directions for avoiding this mistake. The pain and tenderness and resistance may be much less definitely located to the right iliac fossa than is usual in true appendicitis, but, on the one hand, the symptoms of the latter condition are not always typical, and, on the other, the inflammation of the tuberculous glands may be confined to the neighbourhood of McBurney's point. There may even be a tender palpable lump, which is nearly certain to be taken for an abscess, but in this case the tuberculous lymph-gland may be single, and it may be in the patient's interests to remove it, whereas if the lymph-nodes are widely involved nothing can be done, and the operation was therapeutically useless.

Other sources of error have been very infrequent, and are represented in my series by only one or two of each. The catalogue includes *B. coli* pyelocystitis, puerperal sepsis, pneumonia, gonorrhœal peritonitis, carcinoma of the cæcum, solitary ulcer of the cæcum, and tuberculous peritonitis. On a few occasions there has been confusion between appendicitis and perforated duodenal ulcer, pneumococcal peritonitis, pyosalpinx, or cholecystitis, but here, as well as in the case of several of the conditions already mentioned, no harm is done, because operation is the proper treatment.

Confusion with Pneumonia.

It is a very serious mistake to operate on a patient with pneumonia and one which demands constant vigilance if it is to be avoided. I remember one such being sent 20 miles in an open car in January; needless to say, this proved not to be good treatment for the pneumonia, and she died. It is usually stated that if it is pneumonia there will be an alteration of the pulse-respiration rate, and if this sign is present it is, of course, very valuable evidence, but it is far from constant. Table VI. gives the diagnostic features, but the final opinion must be based on the whole clinical picture and not on any one so-called infallible sign.

TABLE VI.—*Early Pneumonia and Appendicitis: Diagnostic Table.*

<i>Early pneumonia.</i>	<i>Appendicitis.</i>
Pain may not be the first sign.	Pain always the first sign.
Pain severe, constant, widespread.	Pain not so severe, paroxysmal at first, more localised.
Vomiting rather uncommon.	Vomiting usual.
Diarrhoea common.	Diarrhoea uncommon.
Facies anxious; alae nasi may be working; herpes common.	Nothing special.
Pulse-respiration rate quickened.	Normal relationship (1 to 3½).
Temperature 102°–104° F.	Temperature 98°–101° F.
Pulse under 100.	Pulse over 100, if temperature is raised.
Tenderness diffuse over right side.	Tenderness over appendix region.
Respirations mostly abdominal, "catchy."	Respirations mostly costal.
Sticky crepitations may be heard.	No.
Rectal examination nil.	Rectal examination perhaps tenderness.

It ought to be remembered that in those cases where violent symptoms come on within 24 hours and the patient is in great pain and distress, with high fever and diarrhoea, it will probably prove to be pneumonia with pneumococcal peritonitis, and the prognosis is grave. If in real doubt, it is better to wait 24 hours in a case of appendicitis than to operate for incipient pneumonia. At the end of that time the diagnosis has nearly always clarified itself.

Patients who are pregnant, or have recently been delivered, are veritable traps for the unwary, and it is wise to approach them with a bias against operation, unless the signs are crystal clear. During pregnancy an attack of right-sided abdominal pain, with vomiting, fever, and tenderness about the appendix, is much more likely to be *B. coli* pyelocystitis, which ought not to be operated on. Occasionally the same mimicry

is seen in unmarried women, or just after marriage. A rigor, the very high temperature, and in some cases (not all) some frequency of micturition will put us on our guard. A bacteriological examination of the urine clinches the diagnosis.

Shortly after a confinement, a very accurate imitation of appendicitis can be given by puerperal (uterine) sepsis, as well as by parametritis. The second mistake does not matter seriously; the former does, as the laparotomy will be useless and the patient may very likely die. In young women with what appears to be appendicitis, especially if the tenderness is rather diffuse over both sides of the lower abdomen, we should consider the possibility of gonorrhœal peritonitis, and it is a moot point whether one ought to operate if the evidence points to that diagnosis. A useful clue may be given by inspection of the vagina and cervix, and by a rectal examination.

As my old teacher Prof. C. A. Morton has recently pointed out, it may be difficult to distinguish between carcinoma of the cæcum and appendicitis, and I have seen a case or two in which the error has been made in each direction when a tender mass was palpable in the right iliac fossa. It is not well known that there is a solitary ulcer of the cæcum or ascending colon, of which I have seen two examples within the past year, in which there is a painful lump which was diagnosed as appendicitis, once by myself and on the other occasion by another surgeon. It is cured by excision.

Appendicitis and the Specific Fevers.—There may be an authentic appendicitis coming on coincidentally with measles or with typhoid fever. I have had two examples of the first and one of the second under my care, and in each case the appendix was acutely inflamed, swollen, and buried in exudate. The combination of measles with this disease is a very serious one. My first case was operated on one Christmas day at a country farm-house. The other children had measles. Perforation of the appendix had taken place; next day the measles rash came out and the boy died of pneumonia and peritonitis. In the second case there was no reason to suspect measles; immediately after the operation the lad had great difficulty in breathing and became dusky, and the next day the right lung was solid with pneumonia. It was supposed that he must have aspirated some vomit, but on the third day a measles rash appeared and the lung suddenly cleared up and the alarming symptoms passed away. No doubt the ether had converted a latent bronchitis, which had given no evidence of its presence, into a severe pneumonia, albeit of brief duration.

THE DIAGNOSIS OF CHRONIC APPENDICITIS.

It is now widely recognised that the diagnosis of chronic appendicitis has been far too frequently made, and that removal of the organ when the patient has not been seen in an acute attack has often failed to relieve the symptoms. Some American writers go so far as to say that there is no such thing as chronic appendicitis, but this is an over-statement. Given wise selection, the number of useless operations need be very small.

The main factor in arriving at a correct diagnosis of chronic appendicitis is to get a reliable history of a definite acute attack. When this is lacking one must proceed cautiously. The most prominent symptoms will be, of course, pain and tenderness in the right iliac fossa. One must first exclude those numerous conditions which may give rise to pain in the right iliac fossa, which give definite evidence of their presence when carefully looked for. Here belong mucous colitis, renal aching, gynaecological troubles, growths of the cæcum, solitary ulcer of the cæcum, psosas abscess, tuberculous spine, nerve-root pressure, &c. But when these have been excluded, there is a large residuum, especially in women, which must not all be labelled and treated as chronic appendicitis if one wishes to avoid much useless operating. This residuum includes a majority group, suffering from the ailment variously described as "mobile cæcum," visceroptosis,

or Lane's chronic intestinal stasis, and a minority group who have an authentic chronic appendicitis. The cause of the pain and tenderness in the first or majority group is dragging and distension of a large, loose, dropped cæcum. On exploration one may also find Lane's ileal kink, an appendix looped up in retention bands (which ought not to be called adhesions), extensive Jackson's pericolic membrane, and general visceroptosis. The pain in such cases is due to a combination of ptosis of the cæcum and adhesions or bands about it, giving rise to kinking or to a concertina arrangement of the cæcum and ascending colon. Obviously it is useless to remove the appendix if the pain is due to such a cause, and here is the main reason for the unsatisfactory surgery we have just referred to.

A careful history will generally help us to distinguish between this condition and true chronic appendicitis. The pain of mobile cæcum is continuous day after day for weeks, months, or years; now better, now worse, but seldom entirely absent. It is often (not always) relieved by recumbency, and especially by taking meals lying down. (This avoids the kinking or concertina-deformation of the cæcum, which occurs when that organ prolapses into the pelvis but is held up here and there by bands. Taking food leads to cæcal peristalsis, which is painful under such circumstances.) The costal angle is narrow and often the kidney is movable. This type of patient is suffering from the virginal form of visceroptosis, not the maternal, so one must not expect to see marked sagging of the lower anterior abdominal wall. Very valuable evidence will be given by a barium meal, showing general visceroptosis, a distended cæcum, perhaps prolapsed and tied by bands, and marked delay in its emptying time.

In genuine chronic appendicitis, on the other hand, the usual history is of periods of pain and periods of freedom from pain. The patient may be able to count the attacks, although there may never have been any rise of temperature. The above-mentioned signs of visceroptosis are absent, and recumbency does not give relief. Sometimes, it is true, one sees a patient with never-ceasing pain due to the appendix, completely and permanently cured by removal thereof, but it requires considerable circumspection to pick these out from amongst the merely cæcal cases.

Patients suffering from pain of cæcal origin ought not to be operated on until good trial has been made of a Curtis belt, liquid paraffin, recumbency for meals, a diet rich in vitamins, &c. If one is driven to operate, or finds the condition during an exploration for appendicitis, my practice, in addition to removing the appendix, is to perform a cæcoplication, not so much to narrow the cæcum as to shorten it, and the results have been very good. Others perform Waugh's operation. In a very few very extreme cases I do a hemicolectomy and have had a few failures and a number of striking and lasting successes. Some surgeons excuse the recurrence of pains after removal of the "chronic" appendix by alleging that adhesions have formed. This must be very rare. In my experience, if the diagnosis of chronic appendicitis is only made in accordance with the principles just described, there will be few if any patients coming back again for recurrent pains after removal of the organ.

LATENT APPENDICITIS.

Chronic inflammation of the appendix may be responsible for symptoms quite different from those already described. These cases of latent appendicitis fall into three groups at least: (1) Irregular attacks of fever, perhaps vomiting, and vague abdominal pains in children and boys and girls of school age, but with no signs localised in the right iliac fossa; (2) symptoms like those of gastric or duodenal ulcer, but usually atypical in some respect (= appendicular gastralgia); (3) profuse hæmatemesis with or without dyspeptic symptoms, associated with a small atrophic impervious appendix.

(To be concluded.)

THE BASAL METABOLIC RATE: ITS DETERMINATION AND INTERPRETATION.

By HENRY F. MOORE, M.D., D.Sc.,

VISITING PHYSICIAN, MATER MISERICORDIÆ HOSPITAL, DUBLIN;
FORMERLY ASSISTANT, HOSPITAL OF THE ROCKEFELLER
INSTITUTE FOR MEDICAL RESEARCH, NEW YORK.

(From the Wards and Metabolism Laboratory of the
Mater Misericordiae Hospital.)

IN his book, "The Science of Nutrition," Lusk¹ says: "In each mammal there is a basal metabolism." By the term "basal metabolism" or "basal metabolic rate" is meant the minimal heat production of an organism, measured from 12 to 18 hours after the ingestion of food (post-absorption state) and with the organism at complete muscular rest in a comfortably warm environment. This minimal heat production may be determined *directly* by actual measurement by means of a calorimeter, or *indirectly* by calculating the heat production from determination of the amount of oxygen used within the organism and the corresponding amount of carbon dioxide produced, together with the total nitrogen eliminated.

Francis G. Benedict² states that the level of vital activity may be inferred from the amount of heat produced; whilst heat is the end-result of glandular and muscular activity, oxidative processes are essential factors in these transformations. Thus, the intake of oxygen is essential to combustion, while the production of CO₂ makes up a very large part of the total oxidative processes of the body. Therefore, if one can measure accurately the carbon dioxide produced, or, better still, the oxygen consumed, a very close estimate of the total heat production, and consequently of the end-results of glandular and muscular activity, may be secured. Thus, by determining the oxygen consumption under suitable conditions in a given time the basal metabolic rate may be calculated.

THE BASAL METABOLIC RATE IN RELATION TO THYROID DISEASE.

The essential function of the thyroid gland is the elaboration and delivery to the organism of thyroxin, a substance which was isolated in crystalline form in 1915³ by Kendall. According to Plummer,⁴ the following statements hold true: (a) Thyroxin is active directly or indirectly in the cells throughout the body and, acting as a catalyst, it hastens the rate of formation of a quantum of potential energy available for transformation on excitation of the cell; (b) hyperthyroidism is the physiological or pathological status of an individual, otherwise normal, when the thyroxin in the tissues is sufficiently increased to hold the basal metabolism above normal; (c) all the phenomena in pure hyperthyroidism are those that attend a sustained elevation of the basal metabolism above normal; (d) the status of the hyperfunctioning adenomatous goitre is the result of pure hyperthyroidism, while that of exophthalmic goitre is not accounted for by a pure hyperthyroidism (possibly here the thyroxin formed is chemically different in a slight way from normal thyroxin); (e) adequate intravenous administration of thyroxin to thyroidless patients, who invariably have a low basal metabolic rate, always restores the basal metabolic rate to normal; (f) the average daily exhaustion of thyroxin by the tissues is from 0.75 to 1 mg.

Boothby⁵ states that by the term hyperthyroidism is meant the clinical syndrome resulting from the action in the body of an excess of thyroxin. From 12-14 mg. of active thyroxin must be present in the body to maintain the basal metabolic rate at the normal level; excess of thyroxin in the organism increases the rate.

A decrease of the basal metabolic rate is characteristic of myxœdema or cretinism, and is due to the inability of the thyroid gland to furnish sufficient thyroxin to the body.

Thus, it is seen that the determination of the basal metabolic rate may be of significance in the study of disease of the thyroid gland. The possible increased basal metabolic rate in active acromegaly and the decreased rate in hypopituitarism suggest that the alteration in the activity of the pituitary gland may change the metabolic rate, but there is little evidence that the secretion of any part of the pituitary gland is concerned with the normal rate of cellular combustion in the sense that its secretion acts, like thyroxin, as a calorogenic agent. There are certain other diseases in which an increased basal metabolic rate is occasionally observed—e.g., severe anæmias and leukaemias; the cause of the increased metabolism in these instances is not known. Du Bois⁶ has shown that increase of the basal metabolic rate in fevers follows Van't Hoff's law of the velocity of chemical reactions with temperature change—i.e., the basal metabolic rate is about doubled for an increase of temperature of 10° C. It is interesting to note, in passing, that in 1919 Kendall⁷ stated that 33 g. of thyroxin had been separated from 6550 lb. of fresh thyroid material. Thyroxin is stated to be 4-5-6-tri-iodo-2-oxy-beta-indole-propionic acid; it is closely related to tryptophane; it is a white crystallisable substance and heat-stable.⁸

METHODS OF ESTIMATING THE BASAL METABOLIC RATE.

The methods available for the estimation of the basal metabolic rate fall under two main categories:—

1. *Direct Calorimetry.*—The heat produced in the metabolic processes is determined in a respiration calorimeter chamber. The apparatus needed is extremely expensive and complicated, and necessitates a number of highly-trained technicians. This method is altogether outside the resources of hospitals, and it is used only in a few institutions especially equipped for research on metabolism.

2. *Indirect Calorimetry.*—Here either the oxygen absorbed or the carbon dioxide liberated in a given time, or both, are measured. From these figures the respiratory quotient can be calculated, and if the nitrogen eliminated in the urine is estimated at the same time it is possible to apportion the oxygen used for the burning of protein, carbohydrate, and fat. The determination of the respiratory quotient and nitrogen elimination are, generally speaking, not necessary in clinical work. "The validity of the method has been established beyond a doubt by the simultaneous measurement of heat by physical means, and of the gas exchange in a respiration calorimeter."⁹

There are two chief methods of indirect calorimetry:—

1. *The Open Circuit Method.*—The external air is breathed and the expired air trapped in a spirometer bell or bag, from which samples can be removed for analysis, and their oxygen and carbon dioxide content determined. The disadvantages of the use of this method in clinical medicine are that it is time-consuming, that the apparatus may be comparatively expensive, and that gas analyses are required, the technique of which is not sufficiently simple for general clinical use.

2. *The Closed Circuit Method.*—Principle: F. G. Benedict of Boston¹⁰ has developed a portable respiration apparatus which measures the oxygen consumption of human beings directly, accurately, and rapidly. A relatively simple technique for the measurement of the oxygen consumption of man has been evolved which necessitates neither large respiration chambers, complicated valves, weighings, nor gas analyses; this is based on the observation that when a subject breathes pure oxygen the amount of oxygen taken up by the blood and used is the same as when ordinary air is inspired. This apparatus measures the oxygen only, for it has been shown that in ordinary work the oxygen consumption is of prime significance in the vast majority of pathological cases. Carpenter and Emmes make the statement that when the measurement of basal metabolism is desired, it is waste of time to attempt any other measurement than that of oxygen consumption supplemented by the controls they have recommended.¹¹ These observers with Hendry¹¹ state that when the oxygen

consumption alone is desired the Benedict apparatus is the best apparatus for short period measurements. Again, where one gas is measured the absorption of oxygen is less affected by abnormalities of respiration than is the production of carbon dioxide.

In the original apparatus and modifications an electric fan (impeller) was placed within the spirometer bell in order to drive the gases within the closed circuit through a soda-lime container so that the carbon dioxide might be absorbed and the gas sent in respirable condition to the mouth of the patient. This electric impeller is apt to get out of order, to heat the circuit at times, and its noise is apt to disturb the patient; it is omitted in the Roth-Benedict apparatus¹² and the original electric impeller and face-mask are replaced by simple rubber valves and a mouth-piece.

The Roth-Benedict Apparatus.

The Roth-Benedict apparatus consists of a spirometer bell, cylindrical in shape (bearing a thermometer at the upper closed end), accurately counterpoised over a pulley

FIG. 1.—Diagram of the Roth-Benedict Apparatus with Kymograph Attachment.

A, spirometer bell; B, water seal; C, soda-lime container; D, expiratory valve; E, inspiratory valve in its housing; F, mouth-piece; G, pulley; H, counterpoise weight, pointer, and kymograph pen-writing tracing; K, time-marker; L, kymograph; T, thermometer.

valve (which shuts at inspiration) is placed on top of the soda-lime chamber, and the inspiratory valve (which shuts on expiration) is situated in a special housing at the end of the inspiratory tube below the body of the apparatus. In this way, when the nose is closed with a nose-clip and the patient connected up with the apparatus, he expires into the spirometer chamber (the spirometer bell rising) through soda-lime where the CO₂ is absorbed, and he inspires pure oxygen from the bell (the bell falling) with a minimum of frictional resistance. Thus, the oxygen consumed over a given time can be measured accurately by a scale adjacent to the counterpoise weight which carries a pointer running on the scale—the pointer falls and rises as the bell rises and falls; or, if a pen is attached to the weight or pointer and allowed to write on a revolving drum with a suitable time-marker (Roth) the test can be recorded and the oxygen consumption measured graphically.¹³ The volume of the oxygen consumed in a given time is then corrected to normal temperature, pressure, and for relative humidity (80 per cent.) according to the laws of Charles or Gay-Lussac, Boyle and Dalton. The Roth-Benedict apparatus is used by the present writer. Prof. Krogh of

Copenhagen has also independently devised a clinical apparatus similar in principle to the Roth-Benedict.*

Having determined the oxygen consumption, this must be compared with standards of oxygen consumption of normal persons of the same size, shape, age, and sex, in order to estimate whether the oxidation processes of the organism, and therefore the basal metabolic rate, are greater or less than normal. Rubner¹⁴ suggested that the heat production of an individual was proportional to his surface area, and E. F. and D. Du Bois¹⁵ devised a linear formula based on height and weight, after the most careful measurements, whereby the body surface could be calculated with an average error of under 2 per cent. Later D. Du Bois devised a simple though slightly less accurate (± 5 per cent.) formula which is:—

Surface area = $W^{0.425} \times H^{0.725} \times 71.84$,
where W = weight in kilogrammes and H = height in centimetres.

On the basis of this formula Du Bois then constructed a height-weight chart by means of which the surface area could be estimated at a glance, and, by using such a chart in conjunction with his standards of normal basal metabolism for age and sex, Du Bois showed that the metabolism of normal adults per square metre of body surface could be predicted with an accuracy of 10 per cent. The height-weight chart of Boothby and Sandiford† is convenient to use; a straight-edge joining the weight and height figures cuts the centre line at the figure for body surface. Benedict¹⁶ criticised this method on the ground that the heat output of the body at rest does not depend on Newton's law of cooling and is therefore not proportional to body surface; consequently Harris and Benedict¹⁷ compiled standards based on weight, age, sex, and height, but the results obtained by using both sets of standards do not differ very markedly (6.5 per cent. higher by Harris-Benedict method). Other standards were devised by Dreyer,¹⁸ and Benedict and Talbot¹⁹ have compiled standards for boys and girls based on weight, and Benedict and Hendry²⁰ for girls at the age of puberty based on age and weight. Boothby and Sandiford²¹ conclude that the Aub-Du Bois standards give the best method available at present for predicting the normal heat production. The best standards for boys and girls ranging in weight from 2.5 to 38 kg. seem to be those of Benedict and Talbot (see Table I).

(D) Harris-Benedict Standard Formulas.

For Males (applicable to boys back to 10 kilos. in weight).

$H = 66.473 + 13.752 w + 5.003 s - 6.755 a$.

For Women (for ages not under 21 years).

$H = 655.096 + 9.563 w + 1.850 s - 4.676 a$.

H = heat production, cal. per 24 hrs. w = weight in kilos.
s = stature in centimetres. a = age in years.

Graphic Method (Roth, see Figs. 2, 3, and 4).—The mouth-piece and conducting tubes having been cleansed and sterilised, the apparatus is assembled. The sealing chamber is filled with water to within a few inches of the top. The absorbing chamber is filled with suitable granular soda-lime (Wilson brand is recommended). The charge of soda-lime can usually be used for several tests, and should be changed when it ceases completely to absorb CO_2 , as shown by bubbling a sample of the air in the spirometer at the end of a test through baryta water by means of a tube connected to a small stopcock placed in the bottom of the respiration chamber. A test thus showing unabsorbed CO_2 should be discarded. After filling the soda-lime container its cover is sealed with a rubber band, and the rubber flutter valve on the cover is examined to see that the lateral slits come barely in contact with each other. This may be regulated by

FIG. 2.—Multiple Thyroid Adenomata (Non-Toxic).

Case H. B.—Female, aged 44. P., 86; T., 98.5° F.; R., 20 (B). P., 73; T., 98.6°; R., 20 (E). Spiro. T., 11.5° C. (B), 11.5° C. (E). Wt., 151 lb. = 68.6 kg.; Ht., 63 in. Bar., 754 mm. Hg. O₂ line = calcs. per hr. = 184 - 106 = 78 mm.; corrected calcs. per hr. = $78 \times 0.952 = 74.2$ (N.T.P.). Area body surface = 2.02 sq. m. (= 2); calcs. per sq. m. per hr. = 36.7 (= 37). Average normal calcs. per sq. m. per hr. = 36 (Aub and Du Bois). B.M.R. = -2.7% (= -3%).

B = just before test.

E = just after test.

drawing the valve more or less over the metal tube. If properly adjusted the rubber valves are almost noiseless and never stick if clean. The soda-lime container is then tightly screwed in position within the inner chamber. The inspiratory valve is also examined prior to the test. Any water of condensation that collects in the lower expiratory tube should be drained away after the test as necessary for so doing arises. The respiration chamber is filled to the required degree with oxygen with a cork blocking the mouth-piece, and the apparatus is tested for leaks by placing a weight on the spirometer bell and noting whether the pointer rises after a few moments. The operator should himself use the apparatus before the test for a few moments—the connexions can be cleansed before use with the patient or a fresh set used. The fasting (15 hours) patient is reclining and resting comfortably, fully relaxed, for at least

half an hour on the couch beside the apparatus before the test; he should not smoke on the morning of the test; he is protected from the cold or visitors, and kept as quiet as possible. He is instructed beforehand as to the nature and requirements of the test in order to gain his confidence and ensure coöperation. His pulse and respiration rates are noted several times during the half-hour rest and his temperature taken. When all is ready the cork is removed, and the mouth-piece is inserted in the patient's mouth with the two lugs between the teeth and the oral flange between the lips

in the measurements. It is better to base the calculation on a short undisturbed period of only four or five minutes than on a larger one which includes vitiated sections. For example, consciousness of the patient of his own respirations, often intensified by his effort to breathe correctly, may cause the degree of expansion of the lungs to vary considerably; such a source of error will generally be revealed by the kymograph, but might readily otherwise pass undetected and introduce a considerable error.

Roth states that further advantages of his graphic method are as follow:—

"It simplifies the technique. It reduces to a minimum the necessary procedures. There are no spirometer readings to be made. Stop-watches can be dispensed with. The kymograph automatically records the time, the oxygen consumption, and, to a large extent as well, the working condition of the apparatus and the behaviour of the subject. The average respiration count per minute is most conveniently obtained from the tracing. One operator only is needed to supervise the entire operation, including the counting of the pulse, to observe the spirometer temperature and the barometric pressure, while at the same time an occasional glance at the kymograph keeps him informed as to whether the test is progressing under desirable conditions. The computations, as ordinarily carried out, are naturally reduced if based on the graph which, furthermore, allows the full advantages presented in the considerably simplified system of calculation presented."

It is to be noted that direct readings from the scale when no graph is used make the test more laborious.

Calculations.

The object desired is the determination of the percentage increase or decrease of the metabolic rate of the subject as compared with the accepted average normal standards which are expressed (Du Bois) in terms of calories used per square metre of body surface per hour. In clinical work the calories elaborated by the patient are calculated from the amount of oxygen he has absorbed during the time of the test; one litre of oxygen absorbed = 4.825 calories; this figure varies slightly according to the proportion of fats, proteins, and carbohydrates oxidised by the subject, but in practical clinical tests the average calculated calorific value of oxygen is

FIG. 3.—Normal Man; to Illustrate Irregular Respiration.

Aged 42 yrs. P., 70; T., 97.4° F.; R., 20. Spiro. T. at B = 10° C.; at E = 11° C. (10.5° C. = av.). Bar., 771 mm. Hg; Ht. = 66 in.; Wt. = 168 lb. O_2 line = calcs. per hr. = 143 - 73 = 70 mm.; corrected calcs. per hr. = $70 \times 0.977 = 68.39$ (= 68.4). Body surface = 1.85 sq. m.; calcs. per sq. m. per hr. = 36.97 (= 37). Average normal calcs. per sq. m. per hr. = 38.5 (Aub and Du Bois). B.M.R. = -4.16% = -4%. If O_2 line = 70 + 4, B.M.R. = +1. If O_2 line = 70 - 4, B.M.R. = -9.

and the nose-clip is applied. Then, after a few minutes, the kymograph is brought into contact with the recording pens, and the respiratory movements of the bell are recorded above the time tracing on the paper of the revolving drum. The upward tendency of the tracing denotes oxygen consumption. The spirometer temperature is noted at the beginning and end of the tracing, and a tracing of about ten minutes' duration is recorded. After a rest the test can be repeated if desired.

Roth states that a kymograph record of the movements of the spirometer bell taken during a test simultaneously with a graphic time record (see Figs. 2 to 4) is the most accurate basis for the measurement of the oxygen consumption of the subject by the method of indirect calorimetry. Further, not only is a permanent record of the test secured, but the oxygen consumption can be more easily and accurately measured by the graphic method than by the method of direct readings indicated by the moving pointer against the millimetre scale, especially with subjects who breathe irregularly. Again, no disturbance of any significance for the interpretation of the test can occur to the patient during the test without affecting the respiration in a manner readily detected from the tracing. Not infrequently, also, the test is started before the patient has returned to the basal condition which a 30-minute preliminary rest period is intended to ensure, but which is apt to be more or less disturbed in the process of starting the test; if, as a result, the metabolic rate has been temporarily increased the respiration curve will readily show it, and any portion of the tracing which does not represent the probable basal metabolic rate of the subject can be disregarded

FIG. 4.—Thyrotoxic Adenomata.

Aged 37 yrs. Wt., 51 kg.; Ht., 169 cm.; Bar. = 768 mm. Hg. Temp. of spiro. 14° C. Temp. of patient: Before, 97° F.; after, 97.4°. Pulse: Before, 84; after, 82. Respir.: Before, 24; after, 22. O_2 line = 157 - 40.5 = 117 mm. = calcs. per hr.; corrected = $117 \times 0.941 = 110.1$ calcs. per hr. Body surface = 1.57 sq. m.; calcs. per sq. m. per hr. = 64.3. Average normal calcs. per sq. m. per hr. (Du Bois) = 36.5. B.M.R. = +76 per cent.

sufficiently accurate—i.e., 4.825 calories per litre of oxygen—assuming 0.82 as the average respiratory quotient.

For very accurate measurement of the heat production the measurement of both respiratory gases is necessary, because the heat value of the unit quantity of oxygen or carbon dioxide varies according to the nature of the foodstuff oxidised. When fat is burned

the heat value of one litre of oxygen is 4.686 calories; when carbohydrate is oxidised the heat value is 5.047 and the protein value is 4.485. Thus, the heat generated as calculated from oxygen consumption or carbon-dioxide production varies with the non-protein respiratory quotient which normally lies between 0.71 for fat and 1.0 for carbohydrate, and to determine the respiratory quotient both gases must be measured. The non-protein respiratory quotient is derived by calculation from a knowledge of the urinary nitrogen excretion over a given period.

The actual oxygen consumption is determined from the fall in the spirometer bell in millimetres as indicated by the pointer on the scale or the rise of the tracing. To shorten the calculation (Roth) a section of the tracing of one-tenth of an hour (six minutes) is taken and the bell is constructed with a volume of 20.73 c.cm. per mm. of its height. Thus, each millimetre fall of the bell or rise of the tracing (rise of the O_2 line) in a six-minute period represents one calorie per hour:—

$$\begin{aligned} 1 \text{ mm. in 6 minutes} &= 20.73 \text{ c.cm.} \\ \therefore O_2 &= 207.3 \text{ c.cm.} = 0.2073 \text{ litre per hour.} \\ 0.2073 \times 4.825 &= 1 \text{ calorie per hour.} \end{aligned}$$

The consumption of oxygen is measured by drawing an average line along the base of the respiration curve, dropping two perpendiculars to the base line at the beginning and end of the six minutes period and measuring the height of the perpendiculars; the difference in mm. represents calories per hour. This figure, which represents the volume of oxygen used by the subject in six minutes, is next corrected for the spirometer temperature, barometric pressure, and humidity (80 per cent., using Wilson soda-lime) by multiplying by a factor obtained from a table.^{22†} The average spirometer temperature is taken from temperature readings recorded at the beginning and end of the test. A change in temperature of less than 1°C . can be ignored, but if a rise of more than 1°C . is noted allowance is made by adding for each degree centigrade of rise of temperature 0.5 millimetre to the total rise of the O_2 line in six minutes.

The next step is the calculation of the calories produced per square metre of body surface; the body-surface area is read directly from the Boothby and Sandiford chart²³ by laying a straight-edge across the figure joining the weight in kilogrammes and the height in centimetres. The figure representing calories per square metre of body surface per hour is compared with the average normal number of calories per square metre per hour obtained from the tables of normal standards (Table I.), and the percentage increase or decrease noted. The latter is given as the basal metabolic rate.

The normal zone of basal metabolism for male adults and non-pregnant women is usually taken to lie between ± 10 per cent., but with ambulatory patients it may be taken to lie between ± 15 per cent. The basal metabolism of children probably varies within a still wider range.

CONDITIONS NECESSARY FOR A SUCCESSFUL TEST.

The following conditions on the part of the patient are necessary for a successful test: (a) Complete coöperation and absence of apprehension concerning the test—the test is often 10 per cent. higher than it should be when the patient is nervous and apprehensive; (b) the test should be performed in the morning with the patient in the post-absorption state—that is, having had a light supper the previous night and no food for at least 14 hours prior to the test; (c) muscular relaxation; (d) a preliminary rest period of at least 30 minutes in a comfortably warm room with the subject in the reclining position on the test couch; (e) body temperature within normal limits; (f) the respirations should be reasonably

regular during the test, but irregularity of the respiration rhythm or depth is more apt to affect the CO_2 excretion than the oxygen absorption.

Interpretation.

The test should be interpreted in relation to the history, clinical condition, and physical examination of the patient and it cannot and should not be evaluated by itself alone. McCann⁹ writes:—

"If the basal metabolism is determined by the most accurate technique, under rigidly controlled conditions, a deviation from the average normal can be properly interpreted only in the light of the most thorough and painstaking clinical study of the case. In the last analysis a diagnosis must rest upon the clinical observations. As an unbiased objective method of evaluating the results of therapeutic measures in thyroid disease, especially as a means of controlling the treatment of hypothyroidism, basal metabolism determinations are invaluable. . . . Metabolism determinations are unsurpassed as an objective means of measuring the severity of hyperthyroidism or hypothyroidism and the response to various forms of treatment."

Du Bois²³ writes:—

"There seems to be a striking unanimity of opinion that the level of the basal metabolism is the best guide to the activity of the thyroid gland. This has a sound physiological and clinical basis. We must remember, however, that we are dealing with a laboratory test, and that it must not be accepted blindly. There are certain limitations which should be emphasised at this point. The technic is difficult, and errors of 10 or 20 per cent. may be made, especially by beginners. Even in the best hands there is a possible error of 2 or 3 per cent. In addition to this there are rather wide fluctuations in the daily metabolism of certain individuals. The first few tests with a thyroid patient may be 10 or 20 per cent. too high. Some normal individuals consistently show rates 10 to 15 per cent. or even more above or below the normal. The chances are that these various sources of error will partially neutralise each other, but if they all happen to fall in the same direction the result will be far from the truth.

"In every disease there is a tendency to variation from the typical which occurs in certain individuals, and there are few hard-and-fast rules in diagnosis. It is very seldom that we should allow any single symptom or laboratory test to outweigh a mass of evidence. A slavish adherence to the basal metabolism test as an index of diagnosis may lead the physician to trouble, first because the test does not always give the true basal metabolism, and second because even the true basal metabolism is not always the indication of the correct diagnosis. God forbid that we make our diagnoses by machinery!"

The basal metabolism may be notably increased in fevers, hyperthyroidism (Graves's disease, thyrotoxic adenomata, and some cases of malignant tumour of the thyroid and thyroiditis, overdose of thyroid substance or thyroxin), many cases of severe anæmias, many cases of chronic leukæmias, after food ingestion, from muscular work and in some cases of hyperpituitarism. The administration of insulin and suprarenal extract usually causes some increase in the basal metabolic rate. The basal metabolic rate may be notably decreased below the normal limits in hypothyroidism, in the clinical conditions myxedema and cretinism, in traumatic shock, and in chronic inanition.

It is in diseases of the thyroid gland that the determination of the basal metabolic rate is of most value in clinical medicine. From an analysis of over 6000 thyroid cases Boothby and Sandiford²⁴ state that 98 per cent. of cases of exophthalmic goitre have a basal metabolic rate of over 10 per cent. above the average normal values of Du Bois and Aub, and only 7 per cent. were within the limits of ± 15 per cent.; 56 per cent. of cases of thyroid adenomata showed evidences of hyperthyroidism with a basal metabolic rate of more than 10 per cent. above normal; the vast majority of colloid goitre cases showed a normal rate and a few showed an increase up to 20 per cent. above normal.

According to Kessel, et alia,²⁵ cases which show the "sympathomimetic" symptoms of Graves's syndrome (tachycardia, tremor, exophthalmos, asthenia, diarrhoea, sweating) without increase of the basal metabolic rate and without goitre are to be considered not cases of hyperthyroidism but

† Given in the author's reprints.

⁹ Grafe studied various forms of tremor and concluded that the metabolism is increased only if the tremors are very marked and that emotion increases the metabolic rate (quoted by Du Bois²³).

of "autonomic imbalance." These cases are called "border-line" cases by Means.

DIAGNOSTIC VALUE OF BASAL METABOLIC RATE.

The use of the determination of the basal metabolic rate in the diagnosis of thyroid disease is stated as follows by Means and Burgess²⁶ :—

"Patients with an outspoken picture of hyperthyroidism invariably show increased metabolism, and those with definite clinical pictures of hypothyroidism invariably show decreased metabolism. Those with goitres, but no signs or symptoms of abnormal thyroid function, for the most part show normal metabolism.

"By inference from the indirect evidence we believe that in these border-line thyroid cases, provided that in the first place a true basal rate is secured, and, provided that certain well-recognised causes for increased metabolism, such as fevers, acromegaly, leukæmia, and severe anæmia, are excluded, the finding of increased basal metabolic rate is strong presumptive evidence of hyperthyroidism. In a similar way, provided that such conditions as starvation, hypopituitarism, and hyposuprarenalism are excluded, a low metabolic rate is strong presumptive evidence of hypothyroidism.

"To that extent, then, the metabolism test is distinctly useful in differential diagnosis. Like all other laboratory tests it should only be interpreted with due regard to all other clinical and laboratory findings, and with due regard for its limitations and pitfalls."

From our own limited experience and from a study of the literature on the subject we have concluded that the test gives useful information for estimating the degree of thyroid deficiency, of thyrotoxicosis and the results of treatment, that it gives considerable information in the differential diagnosis of mild and doubtful cases suspected to have hyper- or hypothyroidism, but that it is not of great value in the diagnosis of frank cases of hyperthyroidism, myxœdema, or cretinism.

A summary of illustrative cases and cases of special interest are given in tabular form (Tables II. and III.).

TABLE II.—Summary of Illustrative Cases.

No. of cases.	Clinical type.	Basal metabolic rate—per cent.		
		Max.	Min.	Aver.
8	Normals.	+11	-3	+3
9	Adolescent and non-toxic parenchymatous or colloid goitres.	+21	-3	+5
2	Non-toxic thyroid adenomata.	+4	-3	—
4	Toxic thyroid adenomata.	+96	+18	+56
5	Frank cases of Graves's disease.	+67	+23	+49
2	Diabetes mellitus.	+11	+10	—
1	Cerebellar disease (with asynergia)—poor coöperation at test. Suggestion of myxœdema disproved by test.	+23	—	—
1	Obesity, "essential" vascular hypertension, imperfect carbohydrate utilisation, tremor, very "nervous."	+8	—	—

In addition to the cases studied from my own wards I desire to thank my medical and surgical colleagues of my own and other hospitals for sending cases for the test.

TABLE III.—Summary of Additional Cases of Special Interest.

	B.M.R. per cent.		B.M.R. per cent.
CASE 1.—Male, aged 18. Non-toxic parenchymatous goitre with colloid cysts	+12	CASE 8.—Female, aged 46. Frank case of Graves's disease. Marked exophthalmos, moderate thyroid enlargement; slight tremor. Moist skin and says she perspires too easily; pulse averages 86, no diarrhoea or constipation and no menstrual disturbance. Clinically mild thyrotoxicosis	+68
After 0.2 mg. thyroxin by mouth for ten days showed fine tremor, nervousness, moist skin, and pulse of 92 to 96 per minute	+41	After 15 days of liq. iodi co., M xv. t.i.d., by mouth, and partial rest in bed. Clinically much improved; exophthalmos only slight and tremor very slight (see below (a))	+1
CASE 2.—Female, aged 17. Tremor; tachycardia (120); thyroid appears "full"; slight lag of upper lid; no exophthalmos; heart normal	+19	CASE 9.—Male, aged 23. Clinically, prior to tests, looked on as an "effort syndrome" or "autonomic imbalance" case. Tires easily; palpitation on exertion; pulse at rest averages 80, but goes up to 110 or 120 on moderate exercise and does not return to normal rate for several minutes afterwards; can feel his heart beating forcibly on slight exertion; hands and feet cyanotic and show loss of tone of skin vessels; marked tremor of hands and legs, especially on left side; periodic diarrhoea; can concentrate on mental work for short periods only; no abnormal thyroid enlargement and no accessory thyroids discovered (thyroid appeared slightly full at last examination); blood-sugar normal; very "nervous." Cerebro-spinal nervous system normal except for brisk tendon reflexes. Had no treatment during the ten months of observation except sedatives and change to the country. No evidence of thymus enlargement by X rays or otherwise. The case is evidently one of hyperthyroidism.	+32 (b)
CASE 3.—Male, aged 30. Slight uniform enlargement of thyroid, tires easily, some palpitation on effort; some tremor; moist skin; heart, lungs, and abdominal organs normal; constipation; polyuria, urine and kidneys normal; blood-sugar normal; loss of weight; rather "nervous"; no hyperthyroid eye signs. Tendon reflexes brisk. B.P. 120/80; pulse 70 at rest, 90 to 100 after moderate exertion—does not return to normal rate for several minutes. Apparently, a "border-line" case—"autonomic imbalance"	+0.5 normal	After 30 minims of Lugol's solution by mouth for 25 days (see below (a)); improved	+33
CASE 4.—Male, aged 22. Uniform thyroid enlargement, tremor on excitement, occasional diarrhoea, moist skin; pulse averages 80, but goes up to 90 on slight exertion; slight exophthalmos (?); moist cyanotic hands. Clinically very mild thyrotoxicosis (perhaps in remission) or "autonomic imbalance"	-6	CASE 10.—Male, aged 17½. Fröhlich's syndrome (hypothyroidism) with diminished glucose tolerance (by courtesy of Dr. Leonard Abrahamson)	Exactly normal
CASE 5.—Female, aged 47. Exophthalmic goitre. Frank case of thyrotoxicosis. Her local physician had been giving her thyroid substance by mouth for three weeks.	+133	CASE 11.—Female, aged 50. Paralysis agitans with pronounced tremor. Patient very apprehensive owing to psychical disturbance	+30
After stopping thyroid medication and rest for ten days	+47	Second test with patient calm	+11
CASE 6.—Male, aged 35. Exophthalmic goitre; frank case, heart enlarged; marked eye signs	+61	CASE 12.—Female, aged 19. Intellectually deficient; dry scaly skin, hair of head has been falling out; partially deaf; some pigmentation of skin of forearms. Question of hypothyroidism in diagnosis disproved by test	+13
After nine months' treatment (rest, general hygiene, X ray) is clinically much improved and able to work but still has thyroid swelling; exophthalmos slightly improved	+18	(a) It is not intended to convey the impression that the effect of iodine, in benefiting cases of Graves's disease, is permanent.	
CASE 7.—Female, aged 39. Frank case of Graves's disease	+97	(b) Tests given in order during the ten months of observation.	
After rest in bed for two weeks and a few X ray exposures	+64		
After a further 13 days' rest in bed and 30 minims of liq. iodi co. (U.S.P.) by mouth per day, patient was clinically much improved; exophthalmos greatly reduced (see below (a))	+48		

PARA-SMALLPOX¹

(SYNONYMS ALASTRIM, AMAAS), AN ACUTE SPECIFIC INFECTIOUS DISEASE DISTINCT FROM SMALL-POX.

By R. P. GARROW, M.D. ABERD., D.P.H.,
MEDICAL OFFICER OF HEALTH, CHESTERFIELD.

It is a matter of common knowledge that there has prevailed during the last few years in certain districts in England, chiefly in the Midlands and north, a disease notifiable as "small-pox." This disease presents clinical and epidemiological features which distinguish it from virulent small-pox as commonly observed in England in recent times and as described in standard English text-books of medicine and in Ricketts and Byles' classical monograph the "Diagnosis of Small-pox."

The features which distinguish the prevailing disease from classical small-pox are so numerous, so striking, and so constant, and their practical significance to physician, epidemiologist, public health administrator, and public is so important that in the following clinical description I have adopted² "para-smallpox" as its name in order to facilitate comparison and contrast between it and the graver disease small-pox.

The disease is, in all probability (?), the same as that known in South Africa as "amaas" (the Kaffir word for sour milk), and in South America as "alastrim" (from the Portuguese *alaster*, meaning "to strew over"), but inasmuch as these foreign names have no obvious meaning in English, I prefer "para-smallpox"—a name which at once conveys the meaning "a disease closely allied to small-pox." The coining of a new name is not intended to suggest the discovery of a new disease, but merely to indicate its recognition as a definite clinical entity—an acute specific infectious disease separate and distinct from small-pox—a disease, moreover, which is fixed in type and does not tend to assume virulence and acquire the death-dealing and disfiguring properties of small-pox.

Personal Experience.

The clinical description of para-smallpox which follows and its contrast with small-pox are based entirely on personal observation of 500 cases occurring in the borough of Chesterfield between October, 1923, and July, 1924, before and during their isolation at Spital and Morton small-pox hospitals. The data were all collected by myself from these patients and their relatives. Any personal error involved therefore is mine, and not that of the ambulance nurse or

sanitary inspector or other person concerned with the outbreak. Thanks to the kindness of colleagues in Derbyshire and elsewhere, I had opportunities for studying para-smallpox for two and a half years previous to its appearance in the borough of Chesterfield. For example, I am indebted to Dr. Herbert Peck, medical officer of health, Chesterfield rural district, for the opportunity of observing cases from North-East Derbyshire. I have also visited Ilkeston, Long Eaton, Doncaster, Gloucester, Middlesbrough, and other towns where the same or a similar mild disease has prevailed, and I am grateful to medical officers of health and medical superintendents of small-pox hospitals in these towns for permission to see their patients.

My experience of classical small-pox is confined to cases seen in the East during the war, but owing to the kindness of Dr. A. F. Cameron, medical superintendent, small-pox hospital, Dartford, I was enabled to refresh my memory of that loathsome disease by a visit in 1922 to the patients from the Poplar epidemic.

Brief Clinical Description.

For brevity and, so far as it goes, accuracy, I cannot better the description of his disease given by a patient in three words: "pimples following influenza." In these words he brought out the three most remarkable clinical features of the disease—first, the primary toxæmia which was almost universally regarded by both patient and doctor as an ordinary attack of influenza; secondly, the focal lesion, which, smaller and more superficial in the skin than the eruption of small-pox, is accurately described as "pimples"; thirdly, the word "following" signifies one of the most striking features of the disease—namely, the fact that frequently the eruption appears after—it may be several days after—the patient has completely recovered from the initial illness.

Analysis of Clinical Signs and Symptoms of Para-smallpox with Special Reference to Comparison and Contrast with those of Small-pox.

1. *Onset.*—The onset of an average case of para-smallpox is gradual, with headache, dizziness, aches and pains in body and limbs, and weakness of legs. These are the commonest symptoms complained of. In addition, there may be shivering, nausea, vomiting, abdominal pain, backache, and sore-throat. No case in this series gave the classical onset of small-pox with rigor, vomiting, lumbo-sacral pain, and rapid prostration. Although not prostrated, the para-smallpox patient usually lies down to recover from what he calls influenza. His temperature in this stage is 100° to 103° F., and subsides by rapid lysis. The recovery from this initial illness is rapid and complete, and in the average case the patient feels perfectly well for the remainder of his attack, including the stage of eruption and convalescence. The influenzal illness leaves behind no feelings of physical weakness or mental depression such as frequently follow ordinary influenzal attacks.

2. *The Pause.*—Whereas in small-pox the eruption appears fairly constantly in the middle of the primary toxæmia—i.e., about the third or fourth day of the

TABLE I.—Showing the Duration of the Prodromal Illness.

Days from onset to eruption	No illness.	2	3	4	5	6	7	8	9	10

						173				

illness—in para-smallpox its appearance is frequently delayed till the patient has completely recovered, and in about one-third of the cases an interval of one to four days of complete intermission of all symptoms occurs between illness and rash. In this

quiescent period or pause patients have returned to school or to work for days. This change in the chronological relationship of the primary toxæmia and the eruption is one of the most striking differences between para-smallpox and small-pox. (Table I.)

In 173 cases, or rather more than one-third, the interval between onset and eruption was six to ten days.

3. *Eruption*.—The eruption of para-smallpox corresponds exactly with that of small-pox in one important respect—*distribution*. Every detail of observation made by Ricketts and Byles on small-pox in regard to the distribution of the rash may be confirmed in the case of para-smallpox. The skin lesions of para-smallpox are, however, on an average, smaller and more superficially situated, not so shotty, and more rapid in their evolution through the stages of macule, papule, pustule to crust than those of small-pox. The final stage usually referred to as scabs or crusts in small-pox may be more aptly called "amber beads" in para-smallpox. Instead of the opaque brown crusts formed of inspissated pus and blood seen in small-pox, the skin of the para-smallpox patient will be found studded with small round translucent bodies varying in size from pin's head to split pea, and in colour from pale straw to dark amber. These amber beads take their size and shape from the pustules which precede them, and may be perfectly dome-shaped or slightly flattened on the top. Their translucency indicates that the contents of the pustule was scarcely pus, but little more than clear or only slightly turbid serum. This *amber bead phenomenon* is best seen about the end of the first week from the appearance of the eruption, and lasts throughout the second week, when it is of great diagnostic help. A few amber beads of perfect shape and correct distribution have frequently been the only objective sign of an attack, and when supported by a history of "flu" a week or two before, are absolutely diagnostic. I have not seen similar skin lesions in any other condition. When the amber beads are shed from the skin there remain small, round, glistening reddish-brown areas which lose their pigmentation slowly and may be still visible some months after recovery from the attack. But pitting is rare, and when it occurs it consists of a fine foveation on the nose, cheeks, and forehead.

4. *Secondary Fever*.—When the eruption is profuse and the pustules are large and deeply situated in the skin as in small-pox (as they sometimes are), there is mild suppurative fever (100° – 101°) in the second week, but this is rare, and the majority of patients never have an ache or a pain or a temperature above 99° after admission to hospital.

5. Other features associated with small-pox of great toxicity were not observed once in this series—namely, prodromal rashes; hæmorrhages. Further, newborn or very young infants, unprotected by vaccination, had hardly any constitutional disturbance, even when the rash was fairly copious. Infants on the breast never missed a feed, and the first thing noticed by the mother was the appearance on the infant of the characteristic spots.

Complications.

Apart from secondary infections of the skin like impetigo, &c., the only complications observed in this series were connected with the eyes. The ophthalmic complications are of great interest and importance. Three inflammatory conditions were seen.

1. *Blepharitis and Conjunctivitis*.—In quite a number of cases lesions occurred in the palpebral and ocular conjunctivæ. In some the margins of the lids were the seat of numerous pocks. These infected or irritated the conjunctiva, giving rise to acute purulent inflammation with considerable discomfort, but in every case recovery was complete without any permanent damage.

2. *Ulceration of Cornea*.—Three cases occurred in which a pustule formed at the corneo-scleral margin.

When this pustule ruptured an ulcer formed at the periphery of the cornea and spread centripetally. This seriginous ulcer was extremely slow in healing and left a small triangular opacity in the outer third of the cornea with its apex towards the centre and base on the periphery. There was no damage to vision.

3. *Keratitis Profunda*.—Two cases of this rare condition provided the most interesting and important of the eye complications of para-smallpox. Both occurred in the right eyes of very young infants—one 12 days old when the eruption appeared, the other aged 9 weeks.

CASE 1.—Female infant, born Dec. 6th, 1923. No prodromal illness. Rash appeared on the 18th—i.e., aged 12 days. Infected from the mother whose eruption appeared on the 10th. Baby successfully vaccinated on the 15th. The infant had a profuse eruption, but was not ill. It had some pustules about the eyes, and there was acute conjunctivitis of both eyes—more especially the right—with some pus. This cleared up under treatment, and mother and infant left hospital well on Jan. 9th, 1924. Three months later my attention was called to the baby's right eye. The upper half of the right cornea was ground-glass-like. There was no conjunctival or ciliary injection, and the pupil was normal in size, shape, and reactions. The baby was referred for treatment to the Royal Hospital.

CASE 2.—The interesting feature about the second case was that there was no indication of anything wrong with the infant's eye during its period of hospital isolation. It was not till a week after discharge from hospital that the mother noticed "a film over the baby's right eye." Male infant born on June 6th, 1924, rash appeared on August 9th without any prodromal illness. Admitted to hospital on August 12th. Discharged on the 30th after an ordinary attack without any eye trouble of any kind. A week after discharge from hospital the mother noticed a film coming over right eye and took the infant to me at the Health Office. The condition found was very similar to that described in the first case—upper half of right cornea steamy and ground-glass-like. My brother, Dr. A. Garrow, ophthalmic surgeon, Glasgow Royal Infirmary, happened to be with me in September, and I am indebted to him for the diagnosis of keratitis profunda in these two cases. Both cases are now under treatment by Mr. H. H. Emmerson, ophthalmic surgeon, Chesterfield Royal Hospital, who has kindly furnished me with the following reports, dated Oct. 14th, 1924.

Oct. 14th, 1924. 1st case. (Under ether.) Right eye; no ciliary or conjunctival injection; under atropine pupil dilates well and evenly; well-marked central opacity of cornea, definitely in the deeper layers; no vascularisation of cornea; fundi normal.

Oct. 14th, 1924. 2nd case. (Under ether.) No conjunctival or ciliary injection; under atropine pupil dilated well and evenly; upper two-thirds cornea cloudy, opacity in the deeper layers of the cornea; no vascularisation of cornea; fundi normal.

Mortality of Para-smallpox.

The mortality of para-smallpox in otherwise healthy subjects is nil. It does not convey an adequate impression of the mildness of this disease to say that no patient in this series of 500 cases or in the 2000 in the county of Derby died of para-smallpox. No case was sufficiently ill from para-smallpox to cause the slightest anxiety as to the issue.

In descriptions of the disease the mortality is usually stated as 1 or 2 per cent., but these deaths are frequently in very young infants or feeble old people, or result from some condition unconnected with para-smallpox. For example, although no case in this series died of para-smallpox, two of the patients died while in hospital—one from uræmic coma occurring in the course of chronic interstitial nephritis, the other from encephalitis lethargica. Another infant, aged 10 days on admission, died about a week after discharge from hospital from a cause unconnected with para-smallpox.

So far as I have been able to ascertain from the literature and from other sources of information, the 1 to 2 per cent. mortality attributed to this disease appears to be made up of similar deaths. My

own opinion is that the case mortality of para-smallpox is nil, or for all practical purposes nil—e.g., same as in mumps, rubella, varicella, &c. Extensive epidemics of this disease have been recorded running into thousands of cases without a death, and in other outbreaks the mortality figure amongst those attacked (including the deaths from prematurity, senility, &c., not properly attributable to para-smallpox) has actually been lower than the general mortality-rate from all causes amongst the population from which the cases were isolated.

From such statistics emerges the amazing paradox that this disease, far from being a cause of death, is actually to some extent a protection against the fatal issue! The suggestion is not so silly as it sounds, for if persons suffering from a harmless disease, never in itself fatal, are taken from overcrowded houses and bad hygienic conditions where they are ill-clad and poorly fed, to a place of safety where they are well fed and cared for, they are at least protected from some forms of death—e.g., death from violence—which in these days of rapid transport and crowded streets contributes materially to the general mortality-rate. It is not surprising therefore that the death-rate should be lower in para-smallpox than in the healthy.

Vaccination Statistics.

Table II. shows the influence of vaccination in the prevention of para-smallpox. No person vaccinated in infancy was attacked under the age of 17 years. No person recently vaccinated was attacked. No person vaccinated in infancy and revaccinated at any age was attacked.

TABLE II.—Borough of Chesterfield. Vaccination State of Patients.

Vaccinated and re-vaccinated: No person attacked.
Vaccinated recently: No person attacked.

					21									

There are many who believe that the identity of this mild disease with small-pox is settled by this prophylactic influence of vaccination alone. In dissenting from this view I would remind them that even the discovery of the virus of small-pox and para-smallpox as identical organisms does not necessarily settle the question. A simple analogy will explain what I mean. The so-called *Micrococcus melitensis* (in reality a short bacillus), discovered by Bruce as the cause of Malta or Mediterranean or undulant fever in man, is quite indistinguishable to bacteriologists from the *Bacillus abortus* of Bang which causes contagious abortion in cattle. Yet nobody would think of suggesting that undulant fever and contagious abortion are the same disease.

Similarly, no discovery which the sciences of bacteriology and immunology may make in regard

to small-pox and para-smallpox can bridge the wide clinical gulf between the two diseases.

Fixity of Type.

Granted that under the name small-pox there exist two diseases clinically distinguishable, the virulent disease commonly known as small-pox and this other mild avirulent and comparatively harmless disease which I have called para-smallpox, there still remains for discussion the crucial question: *Do these two diseases breed true to type indefinitely under all conditions? In other words, can the mild disease, para-smallpox, be trusted implicitly to remain mild and relatively harmless, and never under any circumstances, known or unknown, assume the virulence of small-pox?*

It is unnecessary to emphasise the practical importance of a correct answer to this question. Upon the answer depends administrative action influencing the lives of thousands of sufferers from the disease and involving the expenditure of large sums of public money. It is necessary to examine the evidence with an unbiased mind, and, above all things, to avoid confusing the issue with the vexed question of vaccination. So far as experience in Derbyshire goes, the answer is in the affirmative. During four summers and three winters the disease has preserved the same average level of virulence. The cases in hospital to-day are exactly the same as those seen three and a half years ago. The same fixity of type has characterised other extensive outbreaks of this disease at home and abroad.

Under these circumstances how does it come about that the view of the majority, and more particularly the official view, is that this disease is merely small-pox of depressed virulence which may and does, under largely unknown circumstances, revert to a virulent type and become classical small-pox? Let us examine the evidence on which this view is based—i.e., the occasions on which the mild disease is alleged to have acquired the virulence of small-pox.

Criticism of the American Evidence.

Those who believe in the power of mild disease to acquire the virulence of small-pox frequently point to the course of events in America, where small-pox is stated to be resuming its severe form after a period of extreme mildness and low mortality. It seems to be forgotten that this change is readily explained on the hypothesis of a change in the relative incidence of two diseases, one of which is mild with a mortality of nil, and the other severe with a mortality of anything up to 40 per cent. By mixing these diseases in varying proportions you can obtain a total case-mortality-rate of any figure from nil to 40 per cent. This explanation of the American experience is just as reasonable as the hypothesis that the increasing mortality from small-pox in America is due to the enhanced virulence of a single disease.

Let us examine more closely a specific instance in the American epidemiology of small-pox of "the mild type suddenly assuming virulence"—namely, the outbreak at Windsor, Ontario, in the early part of 1924. The English journal, the *Medical Officer*, of April 5th, 1924, devotes an editorial article to a commentary on the official circular of the Provincial Board of Health of Ontario, issued to the medical officer of health of the province. The article says:—

"It appears that in the last quarter of 1923 there was a mild epidemic of small-pox in Detroit, on the other side of the boundary between Canada and the United States, whence cases were traced to the Canadian border towns, including Windsor, where there occurred in February a fatal case of hæmorrhagic small-pox in an unvaccinated man, which was not, however, definitely diagnosed as such until after his death, and when persons who had been in contact with him were taken ill with the disease in a particularly virulent form. Up to March 3rd there were 40 cases with 12 deaths in Windsor, and in the adjoining districts there were 20 cases, 6 of which proved fatal. As many as 42 cases were traced to the undiagnosed case, the origin of which, however, it was not found possible definitely to determine; in all probability it was due to the Detroit outbreak, an instance of a mild type suddenly assuming virulence."

The official circular from which this description is culled mentions an alternative source of infection—namely, “the northern part of the province where irregular types of small-pox are often seen.” This is omitted in the *Medical Officer's* commentary. Another significant fact, inadvertently omitted from the article referred to, is mentioned in the official circular in giving a classification of the Windsor cases, viz. :—

(a) Mild cases in individuals with a history of an old successful vaccination over 12 years ago; also an occasional unvaccinated case who had been infected in Detroit (the italics are mine).

(b) Severe confluent and semi-confluent cases all in unvaccinated persons.

(c) Haemorrhagic cases all in unvaccinated persons and all fatal.

From this classification the interesting fact emerges that, far from being an instance of a mild type of small-pox suddenly assuming virulence, this was actually an example of the mild Detroit disease preserving its mild type, even in unvaccinated persons in Windsor, in the midst of an outbreak of small-pox of overwhelming severity and high mortality.

South African Evidence.

Let us turn now to the South African evidence. In THE LANCET of Oct. 14th, 1922, Dr. J. A. Mitchell, Secretary for Public Health and Chief Health Officer, Union of South Africa, contributes an important article on Small-pox and Amaas in South Africa. He states emphatically that the mild disease commonly called “amaas” in South Africa “is merely a form of small-pox ordinarily mild and with low mortality, but capable, under largely unknown conditions, of taking on virulent characters and causing the severe disfiguring and highly fatal type of classical small-pox.” He further asserts that: “Here, in South Africa, the belief amongst some medical men and a large section of the public that the disease is not small-pox, and that it is of permanently mild type and comparatively unimportant, has repeatedly led to unfortunate results.” According to Dr. Mitchell, “every Government health officer in South Africa during the past 25 or 30 years has come to the same conclusion.”

This opinion coming from such high authority calls for the most careful examination of the evidence upon which it is based. Dr. Mitchell, in the course of the article quoted, gives four instances where a mild strain of infection, causing disease of the type commonly known as amaas, has become virulent, the later cases being severe and in all respects typical small-pox with a high mortality-rate. These were :—

1. In 1898 Port Elizabeth had 96 cases with 29 deaths (case mortality 30 per cent.) following infection introduced from Graaff-Reinet, where there was an outbreak of the ordinary mild type.

2. Early in 1904 cases of the disease “of remarkably mild type” occurred in the Ixopo district of Natal, the disease subsequently spreading to Estcourt, where, “owing to the mildness of its manifestations, it escaped early detection under the assumed garb of chicken-pox.” The infection later became disseminated throughout the greater part of Natal and took on very virulent characters. The final statistics of the epidemic show a total of 1238 cases with 361 deaths—a case-mortality of 29 per cent.

3. An instance of a similar kind has occurred under Dr. Mitchell's own observations and is described by him in these words: “In 1900 I was research bacteriologist to the Robben Island Leper Asylum. There was at the time some sporadic prevalence of mild small-pox or amaas in the southern suburbs of Cape Town and the Malmesbury district adjoining, and people from these areas daily came to the island to visit friends in the asylum. The first two cases were very mild, but a large percentage of the subsequent ones were typical small-pox of disfiguring and dangerous type. Twenty-one cases in all occurred with eight deaths, a case-mortality of 38 per cent. The patients, all coloured female adults, were lepers, but most of them were strong and in good general health.”

4. “Again, in 1903, whilst I was at Port Elizabeth dealing with an outbreak of plague, cases of small-pox of the

usual mild type occurred amongst natives of the Sunday's River Valley south of Graaff-Reinet. The disease spread down the valley and eventually to the town of Port Elizabeth. The earlier cases were very mild, but later the type became much more severe. The final figures for the outbreak show 222 cases with 17 deaths—a case-mortality of 7·6 per cent.”

Criticism of Dr. Mitchell's Evidence.

This South African evidence is entirely unsatisfactory for the reason that in none of these four instances are we furnished with an analysis of the statistics giving the number of cases and the number of deaths before and after the alleged change in the virulence of the disease.

The evidence required to satisfy a critical mind on this “change of type of disease” is :—

(a) The occurrence of a considerable number of cases of the mild disease of the character described in this article without a death (deaths from other causes excepted). The larger the outbreak of the mild disease without a death, the better is this evidence because it establishes more firmly the mild pedigree.

(b) Reasonably convincing evidence that direct infection from this mild source caused small-pox of virulent type with high mortality amongst a sufficient number of patients to exclude constitutional disease or infancy or senility as contributing factors in the fatal result. To make this evidence reasonably convincing, the possibility of another source of infection of virulent small-pox in the vicinity should be excluded.

As already indicated, Dr. Mitchell's evidence does not satisfy these requirements. In each instance all we are told is that the early cases were “of mild type” or “of remarkably mild type.”

In order to ascertain precisely what Dr. Mitchell meant by the “sporadic prevalence of mild small-pox or amaas in the southern suburbs of Cape Town and the Malmesbury district adjoining,” which he suggests was the origin of an outbreak of virulent small-pox with a case-mortality of 38 per cent. amongst the lepers on Robben Island, I asked the medical officer of health, Cape Town, if he would be good enough to furnish me with information about the cases occurring in Cape Town and district in 1900. Dr. T. Shadick Higgins has very kindly sent me a copy of such descriptions of the cases as were actually recorded in the register of cases treated at the Cape Town Small-pox Hospital.

The Robben Island outbreak commenced in October, so that the group of 13 cases recorded in the register for August and September, 1900, would appear to be the cases involved. Of these 13 cases—

2 are described as fatal.

3 “ “ “ severe confluent (one with loss of one eye).

1 is “ “ confluent.

1 “ “ mild confluent.

1 “ “ medium discrete.

4 are “ “ mild discrete.

1 is not described.

I venture to submit that, had Dr. Mitchell consulted the records before writing his article, he would not have described these cases as a “sporadic prevalence of mild small-pox or amaas.” I further submit that his opinion that mild small-pox or amaas becomes virulent small-pox, is not supported by any evidence which will bear looking into.

Conclusions.

(1) Para-smallpox is a disease sui generis. (2) It is distinguishable clinically from small-pox on the one hand and chicken-pox on the other. (3) It preserves its type as rigidly as does small-pox or chicken-pox or any other of the acute specific infectious diseases. (4) Its mortality amongst healthy subjects is nil, and there is no good evidence to show that the disease ever assumes virulence. (5) Vaccination with the calf lymph used to protect against small-pox is equally protective against para-smallpox. (6) Administrative measures for the control of the disease could with advantage be modified in the light of these conclusions.

BONE IN THE EYE.

By PERCY DUNN, F.R.C.S. ENG.,

CONSULTING OPHTHALMIC SURGEON, WEST LONDON HOSPITAL;
LATE LECTURER ON OPHTHALMOLOGY, WEST LONDON
POST-GRADUATE COLLEGE.

SCATTERED within the realm of human disease are problems in pathology of special and speculative interest, and undeniably among these is the formation of bone in an atrophied eyeball.

This change is not a pathological freak, occurring with a rarity suggestive of an exceptional environment, but one which for many years has been known, more or less exclusively, to ophthalmic surgeons as the natural sequence of degenerative processes. The presence of the bone and the source of its development have led many observers to investigate the problem. In regard to the broad outlines of the pathology there is a general agreement, but upon the question of detail much room exists for the expression of divergent views—views which still belong to the sphere of speculation. In this category is included the source of the osteoblasts which remains, among other details, a matter of uncertainty.

Atrophy of Eyeball and Phthisis Bulbi.

Incidentally an atrophied eyeball may be described as an eye which is soft, shrunken, and commonly flattened, following an attack of irido-cyclitis, such as may be caused by penetrating wounds or intra-ocular operations which have proved unsuccessful, by which the nutrition of the eye has been arrested by the inflammatory changes in the ciliary body.

It may be noted here that Fuchs draws a distinction between an atrophied eye and one the condition of which is known, ophthalmologically, as "phthisis bulbi."¹ In his view phthisis bulbi, so called, implies destruction of the whole of the intra-ocular tissues, such as occurs after complete suppuration of the eye. In this case the eye contracts to the size of a hazelnut or less, whereas an atrophied eyeball retains some semblance to its original formation. Except for cosmetic reasons, in the former case no interference is necessary; on the other hand, in the latter, in the course of time enucleation is expedient.

The Ossification Process.

A period of years is required for the development of the ossification process in an atrophied eyeball—12 years or more. Cases of much earlier dates have been recorded at which ossification has developed. But these are exceptional; nevertheless, the possibility of their occurrence has to be borne in mind.

The mode of detecting the presence of the osseous plates is by means of palpation. Firm backward pressure is needed, and this gives rise to tenderness, which is at once recognised by the patient. At the same time there may not be any sense of hard resistance to the surgeon's fingers, indicating the presence of bone. Again, a patient may make no complaint of an eye in which bone has developed until tenderness is revealed by palpation. The tenderness is probably due to the pressure of what remains of the ciliary body upon the hard bony substance. Palpation of slight degree is not to be relied on; it may elicit no sensation of tenderness, especially as the ossification usually begins at the back of the eye, first developing around the optic disc. The bone also is thickest in this situation, and in the bony plate there is commonly to be seen a round hole, marking the entrance of the optic nerve (vide figure).

Upon reflection it is strange that bone, incidentally of the periosteal type, true bone with definite

Haversian systems, should be evolved out of the degenerated inflammatory products of an eye in an atrophied state. This ossification has been defined as "the final stage of degeneration of the organised inflammatory products of plastic choroiditis" (Parsons). Possibly the eye occupying a confined and isolated space provides the conditions necessary for the development of the ossification process. That bone has been said to have been found in structures of the eye other than the choroid, such as the lens and retina, would seem to lend support to this possibility.

Whether the inflammatory changes in an eye, which are ultimately followed by the formation of bone, can give rise to an infective plastic uveitis in the other eye has not been established. No case of the kind has been proved. Modern observation must concede that so-called "sympathetic ophthalmitis" is not a "sympathetic" but an infective disease, and Hill Griffith has recorded that he has never met with bone in eyes removed for "sympathetic ophthalmitis." Furthermore, this disease is not known to follow pus infections of an eyeball. Its infective origin must, therefore, depend upon some organism, still to be discovered, in common with other infective diseases, the micro-organic source of which has so far defied the efforts of the bacteriologist to determine.

Record of Case.

Appended are the notes of a case of bone in the eye which recently came under my observation.

Mr. X., aged 62, came on Oct. 8th, 1924. His previous history was one of many years of articular rheumatism, for which at intervals he had received treatment at Harrogate, Bath, Buxton, and other centres of hydro-therapeutics. Gradually he made a good recovery, and has now for some years been free from his former symptoms. Suddenly, about 15 years ago, the vision in the right eye failed and blindness ensued. I was unable to gather from him the cause of this beyond the fact that he sought advice and followed the treatment recommended. Since then, at various intervals, his left eye has suffered from severe attacks of iritis. In the course of one of these the right eye became inflamed, and the symptoms suggested glaucoma. An iridectomy was performed by an ophthalmic surgeon. Subsequently the eye gradually became atrophic, and at the time of his visit to me it was shrunken, soft, and flattened. Such, I was told, had been its condition for approximately 12 years. No complaint was made of the shrunken globe; palpation at first revealed no response to tenderness, but when firm backward pressure was made a slight sensation of tenderness was admitted.

Examination of the left eye showed atropine irritation of the lower lid. For some considerable time drops of a 1 per cent. atropine solution had been instilled daily in an attempt to dilate the pupil. But the iris was contracted and adherent throughout, the condition present being one of complete posterior synechia. The anterior capsule of the lens was fairly clear in the central pupillary space. The tension was good; ophthalmoscopic examination was not possible. The vision admitted was 6/nil; improved to 6/18, nearly, with -7 sph. Apart from the defective vision, the complaint made of the eye was an inability to face a bright light, occasional lacrymation, and a sensation of discomfort. The last attack of iritis occurred four years ago; it persisted for six weeks. Since then the eye has been free from any recurrent reaction.

I enucleated the right eye on Oct. 15th, Dr. S. H. C. Air being present and administering the anaesthetic. The figure illustrates the plate of bone found in the eyeball. One or the other of the openings in the back part of the plate would indicate its position around the entrance of the optic nerve.

Actual size.

That these cases are of clinical importance will be inferred from the above, but added to this is their general pathological interest. Having regard thereto, the fact is somewhat strange that it should have escaped the notice of examiners in pathology. The subject suggests a question in an examination paper. For example: "Under what pathological conditions does bone develop in the eye? Describe the pathology of the process. Of what type is the bone? Discuss the views of the origin of the osteoblasts."

THE DICK TEST FOR SUSCEPTIBILITY TO SCARLET FEVER.

BY CLAUDE B. KER, M.D., F.R.C.P. EDIN.,
MEDICAL SUPERINTENDENT, EDINBURGH CITY HOSPITAL;

J. E. MCCARTNEY, M.D., D.Sc. EDIN.,
LECTURER ON BACTERIOLOGY, EDINBURGH UNIVERSITY;

AND

J. MCGARRITY, M.D. EDIN., D.P.H. EDIN. & GLASG.,
MEDICAL SUPERINTENDENT, ISOLATION HOSPITAL, CARDIFF.

ALMOST a year ago Drs. George and Gladys Dick¹ described a skin test for susceptibility to scarlet fever on the analogy of the well-known Schick test for diphtheria. The reliability of this important reaction has been verified by, amongst others, A. Zingher² and by C. F. Branch and F. G. Edwards.³ It may be remembered that Dr. and Mrs. Dick⁴ succeeded in producing scarlet fever in human volunteers by infecting the nasopharynx with a hæmolytic streptococcus obtained from a case of scarlet fever, and evidence has been accumulating in favour of this micro-organism being the specific cause of the disease. An admirable discussion of the whole question will be found in a paper by Dr. Abraham Zingher,⁵ who gives not only an excellent summary of the literature, but also his own results with the test and his experience of the immunisation of 1400 children with scarlet fever toxin. Dr. Zingher believes the test to be "a reliable index of immunity and susceptibility to scarlet fever," and it would appear that in the United States the question of detecting susceptibles and of protecting them by inoculation is being taken up with the same thoroughness which has characterised American work on the Schick reaction and toxin-antitoxin inoculation.

We commenced investigating this interesting reaction about six months ago, and our results have been distinctly encouraging, although, no doubt owing to the use of too weak a toxin, they have not been as consistent as those obtained by Zingher. Nevertheless, they distinctly point to the general reliability of the test, and it is hoped that their publication may stimulate interest in this question in this country.

The toxin, as used by the Dicks, consists of a soluble toxic filtrate obtained from a culture of the specific hæmolytic streptococcus recovered from the throats of scarlet fever patients. A dilution of approximately 1:1000, but varying in accordance with the strength of the filtrates employed, is introduced intradermally, as in the Schick test, in a dose of from 0.1 to 0.2 c.cm., the former amount being considered sufficient. At present, unfortunately, it would appear that the only practicable method of standardisation consists in testing a known human reactor with the filtrate under investigation and comparing the results with those of a filtrate already found reliable.

Strains of Streptococci Employed.

In all, filtrates were obtained from seven strains of hæmolytic streptococci isolated from the throats of seven early typical cases of scarlet fever.

Case.	Sex.	Age.	Day of disease.	Case.	Sex.	Age.	Day of disease.
1	M.	14	3rd.	5	M.	5	3rd.
2	F.	12	2nd.	6	M.	9	2nd.
3	F.	21	2nd.	7	F.	3	1st.
4	M.	16	2nd.				

Secretion from the pharynx and tonsils was obtained by means of a throat swab and immediately spread on 5 per cent. rabbit-blood agar plates, which were then placed at once in the incubator. After 24 hours' incubation a large number of colonies of a hæmolytic streptococcus was found in every case, the zone of hæmolysis round each colony being well marked. Typical colonies were transferred to blood-agar slopes and re-plated on blood agar three times to

ensure purity. Each strain was tested for its fermentative reactions in Hiss's serum-water medium. All strains gave the same result—namely, acid production in lactose, glucose, and salicin, and no action on mannite, raffinose, and inulin. The stock cultures of these streptococci are subcultured at four days' interval in rabbit-blood broth.

Preparation of the "Toxin."

Flasks containing 100 c.cm. lab.-lemco broth pH 7.5, with 0.5 c.cm. defibrinated rabbit blood, were incubated overnight to test for sterility. They were then inoculated from a 16-hour culture of the streptococcus on blood agar, and incubated for five days at 37.5° C. The growth was profuse and the red blood corpuscles completely hæmolyzed. Films were made from each broth culture to ensure that a pure culture of the streptococcus was present. The broth cultures were centrifuged at high speed for 30 minutes, and the clear supernatant fluid then filtered through a tested Berkefeld V filter, using a negative pressure of 200 mm. Hg. The resultant filtrate was carefully tested for sterility on blood-agar plates incubated both aerobically and anaerobically. In no instance did contamination occur. The filtrate was then stored in the ice-box, and when required diluted 1 in 100 with normal saline. This 1 in 100 dilution was sent out in 10 c.cm. rubber-stoppered bottles, each batch of diluted toxin being again examined to ensure its sterility. These toxins are referred to as Nos. 1 to 7, denoting the case of scarlet fever from which the hæmolytic streptococcus was derived. The more recent batches of toxin have been made from 2 per cent. rabbit-blood broth.

It may be mentioned that a hæmolytic streptococcus was obtained at the first attempt from all the seven cases examined. Most of the work was done with filtrates Nos. 3, 4, 5, and 6. Of these No. 3 appeared to be weaker than the others and is chiefly responsible for lowering the general percentage of positive results. Ultimately it was used in lower dilution, 1:750 and 1:500. The other three filtrates were tested only, and while all gave consistent results, one of them, No. 2, gave a lower percentage of positive results than the other two, and may be considered analogous to No. 3.

The Reaction.

The technique is identical with that of the Schick test, and the diluted toxin must be introduced into the skin with the same precision if reliable results are to be obtained. A control with heated toxin should always be employed as pseudo-reactions are liable to occur, particularly as age advances. The toxin is much more resistant to heat than that of diphtheria and requires boiling for one hour before it can be used as a control. A positive reaction resembles very closely that of Schick, an inflammatory area about the size of a shilling appearing at the point of inoculation, varying in intensity from a deep red with some induration to a faint pink with none. An interesting difference, however, is that the Dick reaction appears much earlier and may be recognised at from four to six hours after inoculation. It is probably at its best within 24 hours; indeed, we found that the results given by a 12-hour reading had seldom to be altered on subsequent inspections, and that in some subjects the reaction was less intense at the 24-hour reading. Nearly all our reactions, moreover, had completely disappeared in 48 hours and pigmentation was not observed. Zingher, however, reports that the reactions may be sufficiently pigmented to be visible after six or seven days, and it is quite probable that our filtrates have been too weak. He explains the rapid appearance of the Dick reaction by the fact that the local action of scarlet fever toxin is primarily on the capillary blood-vessels.

Pseudo-reactions have not been very common, a fact readily explained when it is considered that the tests were made chiefly in children. Owing to the usual lack of pigmentation of the true reaction it is practically impossible to distinguish them unless control tests are used.

Results.

We have tested at the Edinburgh City Hospital 883 individuals in all, 441 of whom were scarlet fever

patients at different stages of the disease, and 442 were either patients with other diseases, chiefly diphtheria, measles, and whooping-cough, or members of the staff and their children. Our first observation was certainly impressive. It was thought advisable to make the first trial of the reaction on the medical staff, numbering six. Of these three had had scarlet fever and all were negative. The other three had not had the fever and two were positive. The third was negative, but it was already known that his blood serum gave a positive Schulz-Charlton reaction, blanching a scarlet fever rash, and that he was therefore almost certainly immune.

Table I. shows the percentage of positive results obtained at different ages in the 442 individuals not suffering from scarlet fever. In the last column we have taken the liberty of showing Dr. Zingher's percentages, obtained from a very much larger number

TABLE I.—Showing Percentage of Positive Dick Tests in 442 Individuals not Suffering from Scarlet Fever.

Age-period in years.	Total.	Negative.	Positive.	Positive percentage.	Dr. Zingher's positive percentage.
0- $\frac{1}{2}$	4	4	0	0	44.8
$\frac{1}{2}$ -1	14	13	1	7.1	64.2
1-2	35	21	14	40.0	70.7
2-3	28	9	19	67.8	67.8

50-	4	4	0	0	—
Totals ..	442	214	228	51.5	—

(4570) of cases. Our own numbers, of course, are too small to give reliable results. The figures suggest, however, that, as in the case of diphtheria, immunity to scarlet fever is not acquired as early in Edinburgh as it is in New York. Our percentages, moreover, seem to show that susceptibility to scarlet fever is highest just at those ages at which the fever is found most frequently to occur. Of the persons included in Table I., 45 gave a definite history of a previous attack of scarlet fever. Of these only eight gave positive reactions, the remainder, 80 per cent., being found to be negative. When it is considered that histories are not always accurate, this result may be regarded as reasonably satisfactory.

Table II. refers to the 441 scarlet fever patients examined and shows the percentage of positive and negative reactions at different stages of the disease. It will be noticed that 73 per cent. of the patients tested in the first three days of their fever gave

TABLE II.—Showing Results of Tests in 441 Scarlet Fever Patients in Different Stages of their Illness.

Stage of disease.	No. tested.	Positives.	Positive percentage.	Negatives.	Negative percentage.
In first 3 days ..	23	17	73.9	6	26.0
From 3rd-6th day ..	103	60	58.2	43	41.6

Sixth ..	24	1	4.1	23	95.8
Over six weeks ..	41	3	7.3	38	92.6

positive reactions. This we admit to be a very unsatisfactory result as Dr. Zingher reports 100 per cent. positive at this early stage, and on the analogy of the Schick test his experience is what would naturally be expected. Our comparative failure points to a

probable weakness of our toxin, and it is obvious that faint or doubtful Dick reactions have very little chance of being detected against the background of a brilliant scarlet fever rash. It is not improbable that many slight reactions were missed.

On the other hand, allowing for slight irregularities in the table due, no doubt, to the small number of cases, the decline in susceptibility in successive weeks is demonstrated satisfactorily enough by our figures, and certainly suggests the general accuracy of the test. One hundred patients who had been found positive before the eleventh day of illness were re-tested. Sixty-four re-tests were made before the sixteenth day and 81.2 per cent. were negative. Thirty-six re-tests made between the thirtieth and fortieth days of illness gave a negative percentage of 75, the difference suggesting that a higher proportion of these late tests were made with a weak filtrate. Combining these groups it was found that 79 per cent. of 100 patients, originally positive, became negative by the fortieth day.

Two other experiments were made. Eleven individuals, all positive, were re-tested with a toxin, diluted not with saline solution, but with convalescent scarlet fever serum, which was known to produce a Schulz-Charlton blanching reaction on scarlet fever rashes. All were found to give completely negative results. Five positive susceptibles were protected with subcutaneous doses of from 3 to 5 c.cm. of convalescent serum and 48 hours later tested with an active filtrate. It was expected that the reaction would be prevented. Unfortunately this experiment failed completely, and all five patients gave good positive reactions. The failure in this case might be held to depend either on the weakness of the convalescent serum, although it gave a positive Schulz-Charlton test, or on an insufficiency in the amount of the dose injected.

Conclusions.

There appears to be no difficulty in obtaining from the throats of early cases of scarlet fever hæmolytic streptococci from which may be prepared filtrates which, when suitably diluted, may be safely injected intradermally and which cause a local reaction in persons who are presumably susceptible to scarlet fever or who are actually suffering from its early manifestations. This reaction is not liable to occur in the vast majority of persons who have already had scarlet fever, and in scarlet fever patients tends to become negative as convalescence advances. As regards those individuals who, not having had scarlet fever, nevertheless give negative reactions, it may be assumed that they have, as in the case of diphtheria, acquired immunity by exposure to subinfective doses of virus at some previous period of their existence. The chief difficulty at present is to standardise the toxin. If it is too weak the results will be unreliable the proportion of positive reactions being unduly low, as we are convinced is the case in this series of observations. One of us had, in the early days of the Schick reaction, equally unsatisfactory results, the commercial toxins then supplied giving perhaps 10 per cent. or 15 per cent. of positive results at age-periods at which nowadays 70 per cent. or 80 per cent. may confidently be expected. This difficulty can to some extent be overcome by carefully comparing the results of different filtrates on known human reactors. It is probably wise, when a satisfactorily acting filtrate is obtained, to use it exclusively, and we have no doubt our findings would have been much more consistent if we had done this from the first. Our work is still being carried on, and with the experience already gained we hope to obtain better and more convincing results.

A STUDY IN INFANT FEEDING.

FOOD REQUIREMENTS OF INFANTS.

By DONALD PATERSON, M.B. EDIN.,
M.R.C.P. LOND.,

PHYSICIAN FOR DISEASES OF CHILDREN, WESTMINSTER HOSPITAL,
HOSPITAL FOR SICK CHILDREN, AND THE INFANTS
HOSPITAL, WESTMINSTER;

AND

RUTH DARBY, M.B., CH.B. BIRM.,
SENIOR HOUSE PHYSICIAN, THE INFANTS HOSPITAL.

In this study an attempt has been made to reduce to some sort of order the clinical experience of ourselves and others in regard to infant feeding and to formulate some rules which may act as a "stepping off" place for those about to undertake the direction of feeding infants.

From the first it must be understood clearly that the healthy normal infant and the under-weight infant present different problems, and therefore separate rules have been laid down for each group. We consider that the first essential for anyone practising infant feeding is to think in terms of the amount of food required in 24 hours rather than in the individual feeds. A rough guide obtained by the study of 50 normal or overweight thriving infants is given below. It will be noted that the amounts mentioned are the amounts of the different foods per pound of body-weight per day. Although not strictly accurate in all cases, it is much nearer the truth than feeding infants by their age. The fatter and more above average weight the infant is, the less food he requires per pound of body-weight per day. Some infants are active, cry a lot, and require more food to make them thrive. These are more often than not male infants. Other infants sleep well, are inactive, and thrive on very little food, and most often these are girls. In warm weather all infants require less food than in a cold, stimulating atmosphere.

The individual infant, then, must be studied, and there is no rule, nor can there ever be any rule, applicable to all infants. It cannot be emphasised too strongly that the infant itself is the final judge in this most important point in infant feeding.

Guide for Normal Infants.

We believe that the following is near the truth in most cases of infant feeding and worth recording:—

Breast Milk.—The average full term breast-fed infant gets from $2\frac{1}{2}$ – $2\frac{1}{2}$ oz. of breast milk per pound of its body-weight in the day. That is, the average infant weighing 10 lb. requires from 22–25 oz. of breast milk in 24 hours. If fed five times in 24 hours each feed would consist of 5 oz. of breast milk.

Whole Cow's Milk (Boiled or Unboiled).—Since to cow's milk both sugar and cream (as dairy cream or emulsion of cod-liver oil) have to be added, the amount of cow's milk is found to be $1\frac{1}{2}$ oz. per pound of body-weight in the day. Enough water must be added to bring the total of the feed out to $2\frac{1}{2}$ oz. per pound of body-weight in the day. Sugar should be added in the quantity of one level teaspoon ($\frac{1}{2}$ dr.) per pound body-weight per day. A teaspoonful of cream or emulsion of cod-liver oil should be given three times in the day.

Dried Milk (Full Cream) (Glaxo, Cow and Gate, Ambrosia, &c.).—Two heaped teaspoons (2 dr.) per pound body-weight per day with sugar added—one level teaspoon ($\frac{1}{2}$ dr.) per pound body-weight per day. This should be dissolved in $2\frac{1}{2}$ oz. of water per pound body-weight per day. That is, a 10 lb. baby fed four-hourly (five feeds) would be given 20 dr. of dried milk and 5 dr. of sugar dissolved in 25 oz. of water in the day. That would be five feeds of 5 oz. of the mixture.

Dried Milk (Humanised) (Prescription Glaxo, Humanised Trufood, and Allenburys No. 1).— $2\frac{1}{2}$ dr. dissolved in $2\frac{1}{2}$ oz. of water per pound body-weight per day.

Guide for Wasted Infants.

In dealing with under-weight infants the problem of infant feeding presents many difficulties. Having excluded those cases of organic disease and gross congenital malformation, and decided that the case is one of the so-called idiopathic type, an examination of the hygiene and management of the child will, as a rule, reveal the source of error. Just as when dealing with premature infants the intake of food must be increased greatly per pound body-weight per day, so the same rule applies in dealing with the under-weight full term infant. The same difficulty, which is fundamental, also arises—namely, the ability of the under-nourished infant to digest a sufficiently large quantity of food to make it thrive without upsetting its digestive system.

It is stated by some authorities that when calculating the feed of an under-weight infant it should be calculated on the weight it should be for its age (the expected weight) rather than the weight which the infant actually is. We have never found this to be the case. The actual amount required lies somewhere between the amount calculated on the actual weight and the expected weight. To simplify matters, we have analysed 50 cases of malnutrition in infants who were doing well although grossly under weight. The following are our findings:—

Sweetened Condensed Milk (Nestlé's).—3–4 dr. (teaspoons) per pound body-weight in the day with a teaspoonful of emulsion of cod-liver oil three times daily.

Dried Full Cream Milk (Glaxo, Cow and Gate, Ambrosia, &c.).— $2\frac{1}{2}$ dr. (heaped teaspoons) per pound body-weight per day with sugar $\frac{1}{2}$ dr. per pound body-weight per day, and emulsion of cod-liver oil as before.

Dried Humanised Milk (Prescription Glaxo, Humanised Trufood, Allenburys No. 1).—3 dr. (heaped teaspoons) per pound body-weight per day.

Cow's Milk (Unboiled, Boiled, or Peptonised).—2 oz. per pound body-weight per day with emulsion of cod-liver oil, sugar, and water added as before.

Conclusions.

The following are the amounts per pound body-weight per day of various foods which should be given to—

(a) **Thriving Infants.**—Breast milk, $2\frac{1}{2}$ – $2\frac{1}{2}$ oz.; whole cow's milk, $1\frac{1}{2}$ oz. with sugar $\frac{1}{2}$ dr.; dried full cream milk, 2 dr., with sugar $\frac{1}{2}$ dr.; humanised dried milk, 2 dr.

(b) **Wasted Infants.**—Sweetened condensed milk, 3–4 dr. plus emulsion of cod-liver oil; dried full cream milk, $2\frac{1}{2}$ dr., with sugar $\frac{1}{2}$ dr.; dried humanised milk, 3 dr.; cow's milk, 2 oz., with sugar $\frac{1}{2}$ dr.

To each infant a teaspoonful of cream or cod-liver oil emulsion should be given three times daily before its feed, and the total of the feed, whether cow's milk, dried milk, or condensed milk with water added, should not exceed $2\frac{1}{2}$ oz. of fluid per pound body-weight per day.

A NEW nursing home for patients of limited means has been recently opened in the suburbs of Liverpool in connexion with the Liverpool Stanley Hospital. As the result of a large legacy by the late Mr. Robert Davies a mansion house with extensive grounds has been acquired some three miles from the centre of the city in open country, and has been converted into an up-to-date private hospital with 30 beds. There is an admirable operating theatre, and it is hoped shortly to provide an X ray department. The rooms are attractively panelled and of lofty proportions, and are arranged on two floors connected by an electric lift. Although in close association with the Stanley Hospital, the home is intended to be open to all persons of limited means. It is proposed to charge 3 guineas a week for beds, curtained off in rooms of two, three, or four each, and 4 guineas for single-bedded rooms. Professional fees will be reduced proportionately.

Medical Societies.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.

A MEETING of this Society took place on Jan. 23rd, when Colonel L. W. HARRISON, the President, delivered an address on the

Value of the Scientific Outlook to the Worker in Venereal Diseases.

The President said that in the course of his work, which brought him into contact with many specialists in venereal diseases, he had formed the opinion—which he would be glad to have grounds for changing—that many clinicians worked too much on empirical lines. They were content to follow along paths recommended by some enterprising author without any clear idea of the principles which should govern their line of action. Often also he found clinicians and pathologists working in compartments, entertaining some little mutual suspicion of one another, when the fact was that coöperation between these two classes of workers was essential to progress. Much of the criticism which had been levelled at the reliability of serum tests of syphilis sprang from a lack of knowledge on the part of many clinicians of the scientific principles and technique of the tests, and consequent inability to understand the point of view of the pathologist. He had heard clinicians criticise particular results as contrary to the clinical findings when it was clear to anyone with a knowledge of the tests in question that the pathologist most probably never intended the interpretation of his report which had been made of it by the complaining clinician. Sometimes, for example, a pathologist spoke of a "weakly positive" reaction, and the clinician, suspecting that the patient was suffering from syphilis, seized upon the word "positive" and used it as his justification for making the diagnosis of syphilis. A little knowledge of the technique and a little conversation with the pathologist would have prevented his acceptance of a "weakly positive" report as justifying anything more than a suspicion, and would have made it clear to him that between the plainly syphilitic reaction and the clearly negative there was a zone into which some non-syphilitic serum now and then wandered.

It would be a great gain, Colonel Harrison continued, if clinicians would study more closely the pathological processes and have more sympathy with laboratory work. Workers in venereal diseases, perhaps more than in any other branch of medicine, had occasion to be grateful to laboratory research. He need only mention a few examples. The arsenobenzol compounds were largely the product of pure research. The bismuth treatment owed its existence to a surmise by a chemist that from its chemical structure bismuth should be anti-spirochætal. To the laboratory were due the serum tests of syphilis and the discovery of the micro-organisms of that disease and of gonorrhœa. Histologists had shown the pathological processes at work in both these diseases, and from them much had been learned of the real problem in treatment as well as something of the lines on which to solve the problem. The histologist also had shown intimately the toxic effects of the anti-syphilitic treatment, and the biochemist had indicated some of the ways in which the toxic effects might be avoided. These were only a few of the debts which the clinician owed to the laboratory worker. Colonel Harrison also spoke of the value of a laboratory training to the clinician. Habits of thought which were developed in laboratory research assisted him greatly in solving his clinical problems. The laboratory worker had the advantage over the clinician that his observations could be more exact, he obtained his results much more quickly, and wrong processes of thought were sooner corrected. Many pitfalls would

be avoided if such methods of thought were adopted more extensively by clinicians. He illustrated his remarks by a reference to criticisms of the vaccine treatment of gonorrhœa. Many of these criticisms were based merely on desultory observations, without any exact computations of results as to complications, period of infectivity, or the possibility of the vaccine employed in a particular case being an anti-immuniser. There was too much generalisation from the mere impression that in a given set of cases the non-vaccinated did as well as the vaccinated.

The pathologist, Colonel Harrison concluded, as well as the clinician, had much to gain from closer coöperation. The pathologist made up his vaccines from such strains as came to him, but everyone knew that strains of micro-organisms varied in their immunising power. The pathologist had no means of knowing whether he was putting a majority of good immunisers or the reverse into his vaccine, and there was little wonder that the clinician gained a bad impression. The clinician might help a little, at any rate, by his observation of the immunising powers of different strains on the patients who provided them. Two workers by coöperation could at least work out the problem in a way which would be impossible to either of them singly.

Vaccine-therapy of Gonococcal Infections.

Dr. P. N. PANTON then opened a discussion on the Vaccine-therapy of Gonococcal Infections. His remarks were limited to a description of some original experimental work not yet completed which it was desired should not be published at the moment.

Dr. ARNOLD RENSHAW said that in the treatment of gonococcal infections by vaccine-therapy there were four things to be considered: (1) Specific vaccine-therapy for the gonococcus; (2) specific vaccine-therapy for associated organisms; (3) non-specific vaccine-therapy; (4) general conclusions. The significant facts with regard to gonorrhœa were its great tendency to relapse, its tendency to become chronic, and, when cured, the ease of reinfection. This indicated poor immunity response, and supporting views were the variable ocular resistance to infection, one eye often showing more reaction than the other, and also the length of time the organisms could remain alive in the prostate, as evidenced by Cobbledick's investigations. A further difficulty with regard to vaccine treatment when using stock vaccines was the number of strains of gonococci which existed. Torrey, in 1907, claimed at least seven different strains, and after further work, which was still proceeding, this investigator believed that it was not possible to demonstrate definite groups such as occurred amongst pneumococci and even meningococci. A study of 50 strains had shown that certain general strains existed possessing antigenic properties common to a considerable part of the "whole" species. There were, however, amongst recently isolated organisms a large number of variants which showed no specific agglutination towards each other, but which quite often showed some specific relationship to one or more of the specific strains. These variants overlapped in such a way that it was not possible to divide them into special groups. After many references to literature, the speaker's general conclusion was that too much attention had been focused upon opsonins, &c.—namely, on the molecules surrounding the gonococcus—and not enough on those molecules which would "bang their way through the bacterial envelope." In other words, chemo-therapeutics must be developed. Too much attention had been paid to a study of gonorrhœa, and too little to a study of the gonococcus. The chemistry of this organism must receive adequate attention. Vaccine-therapy of gonococcal infections must ultimately give way to something better, more vigorous, more decisive in action, and the diagnosis of gonococcal complications must be neater, more precise, and more generally applicable. Until that time came it behoved bacteriologists not to blind themselves to the deficiencies of the methods now available, but to look ahead to more

precise methods and to more adequate means, and to assist the clinician by studying other means of dealing with this organism. The sooner one admitted this position, and the earlier one became completely and entirely dissatisfied with the state of affairs, the sooner would efforts be launched along newer lines of attack.

Discussion.

Mr. T. P. BEDDOES agreed with the President that what was needed was greater harmony between the clinician and the pathologist. The individuality of the Englishman was rather a barrier. As shown by the papers read that evening, clinical work on this subject was capable of very great advance.

Major A. T. FROST said that, with regard to a remark by the President in his address earlier in the evening, he really thought the pathologist would have to take the bull by the horns and give the clinician an idea of what he had got to do to confirm a diagnosis if it was not strongly positive or negative. With regard to the particular point at issue—namely, the gonococcus—there he thought the pathologist was to blame, for he made a vaccine, labelled "gonococcal vaccine," and left the clinician to find his own way with regard to dosage. This Society, he thought, might be very well occupied in trying to standardise dosage. The gonococcus appeared to him to be a very fickle and dangerous organism. A good many stock vaccines prepared in large quantities were probably not of much value, and yet those vaccines were used for the purpose of drawing conclusions. The question of local immunity also should be followed up.

Major W. DE M. PEYTON believed that the vaccines had hitherto been given at too short intervals, and said his experience was that the interval between each dose ought to be lengthened out. A very excellent adjunct to vaccine-therapy, he thought, was the protein shock method which had recently been discussed, and he described his experience of this method, which he believed to be superior to the too frequent repetition of the vaccine. It had been his experience during the past few years that vaccines given at very frequent intervals were rather liable to destroy immunity, and perhaps workers had been rather encouraging the gonococcus to digest its own antibodies.

The PRESIDENT said that many new points had been raised that evening, but the discussion had made at least one thing clear—namely, that team work was essential, and that, as he had suggested in his address, the pathologist must collaborate with the clinician, and vice versa.

Dr. PANTON, in replying on the discussion, referred to the point raised by Dr. Peyton as to the frequency of dosage. He had often felt, in his own limited experience of giving vaccines, that one was in danger of breaking down immunity rather than of increasing immunity if vaccines were given over too long a space of time.

Dr. RENSHAW agreed that vaccines could be given too often. It was rather a question of over-sensitisation, so that one got a too vigorous tissue response to a very weak dose.

LISTERIAN SOCIETY.

At a meeting of this Society, held at King's College Hospital on Jan. 21st, Mr. C. P. G. WAKELEY being in the chair, Sir BERKELEY MOYNIHAN delivered a lecture on

Some Aspects of Cholelithiasis.

He began by giving a few statistical figures and then went on to explain the possible modes of infection of the gall-bladder, and illustrated this part of the lecture by a series of very beautiful lantern slides of microscopic sections of the entire thickness of the wall of the gall-bladder. These slides showed round-celled

infiltration beginning either in the submucosal or subperitoneal coats of the gall-bladder according as to whether the infection was conveyed either by the bile-ducts or by the blood-stream. Typhoid fever was always blood-borne, never bile-borne. The lecturer then laid emphasis on the fact that gall-stones were evidence of preceding gall-bladder disease, with the one exception of the single cholesterol stone, which gave rise to but did not follow inflammation of this viscus. He was at present engaged in research work on the cholesterol content of the blood, finding that in all cases of gall-stones there was a hypercholesterolaemia, and he showed charts comparing this with a similar condition found in infections of the urinary tract, during pregnancy, and in the premenstrual cycle. It was possible in every case of multiple stones to arrange the stones into three and sometimes four groups, and he considered that this fact indicated that the gall-bladder had been subjected to waves of infection. The lecturer cut out what he regarded as a pathological gall-bladder; one where its walls were thicker and less resilient than normal; where the typical blue colour was wanting; where the peritoneal covering had lost its normal sheen; and, most important of all, where there was a deposit of fat under the peritoneal coat of the gall-bladder. Such a viscus should invariably be removed whether it contained stones or not.

Sir Berkeley Moynihan went on to describe some of the difficulties in diagnosis by X rays, pointing out the fallacies which might arise in all but those cases where the gall-bladder gave a denser shadow than the gall-stones. It was important in all cases to employ the barium meal radiography, for by this means it was possible to show pressure displacement of the stomach, duodenum, and colon by a large distended gall-bladder or traction displacement by a shrunken adherent gall-bladder.

Finally, the lecturer urged his audience to cease regarding gall-bladder surgery as anything but the most difficult branch of abdominal surgery. It was not sufficient to be a good abdominal operator; long and uninterrupted experience of this particular branch was the all-important essential.

MANCHESTER MEDICAL SOCIETY.

A MEETING of this Society was held recently, Prof. G. R. MURRAY, the President, being in the chair.

Dr. G. J. LANGLEY read a paper on the

Use and Abuse of Digitalis.

He pointed out that abuse might be heaped upon the drug for two reasons: (1) its use under erring conditions, or (2) the use of an ineffectual preparation. The reputation of the digitalis group appeared to rest upon its power to increase the force and effectiveness of the cardiac stroke, but unequivocal evidence in the field of experimental pharmacology was difficult to find. The great complexity of cardiac problems made the interpretation of experimental results very difficult. Four or five factors determining the force of a cardiac stroke at once arose to the mind—e.g., slowing, increased intake, raised peripheral pressure, myocardial nutrition, carbon dioxide exchange. When the results obtained in undoubted cases of auricular fibrillation were considered, the whole aspect of the matter changed, and it was in this group that brilliant results were almost always obtained. Yet here again for complete success two factors were essential: (a) auricular fibrillation and (b) adequate dosage. The dosage of the drug necessary to produce effect, the various methods of physiological assay, and the toxic effects were discussed by Dr. Langley. Reasons were given for the belief that the optimum therapeutic dose and the toxic dose lay very near together, that the most important effect of the drug was the delay caused in bundle conduction, but that some effect was produced on the ventricular muscle,

as indicated by the inversion of the electrocardiographic T-wave. Eggleston's massive digitalis method was next discussed. A strong reason for the wider adoption of this method was that by its adoption it was possible to save the patient much time and discomfort. The method was reserved for fibrillation at high speed with relative or absolute cardiac failure, and the dose was calculated in terms of cat units. Particulars of 16 recently tested cases were given. The response in all cases except one was most successful and the rapidity of action saved much suffering. Eight hours after the dose the patient was relatively comfortable, and the pulse-rate in nearly every case was 80 per minute or less. In one case the drug appeared to have a definitely toxic effect upon the heart, the pulse speed being raised and the form of the electrocardiogram entirely changed. It was finally submitted that digitalis was specific for the control though not for the cure of auricular fibrillation, that it was likely to be useless and possibly dangerous in other diseases, that the therapeutic and the toxic dose lay very close together, and that massive digitalis dosage was both reasonable and desirable in suitable cases.

WEST KENT MEDICO-CHIRURGICAL SOCIETY.

A CLINICAL meeting of the Society was held at the Miller General Hospital, Greenwich, recently, Dr. H. S. KNIGHT, the President, being in the chair.

Exhibition of Cases and Specimens.

Mr. C. A. JOLL showed: (1) A woman, aged 52, who suffered from dyspepsia. She was unable to take solids, and had pain after food. At operation there was no trace of ulcer. For the visceroptosis the ascending colon was fixed and the appendix removed. The futility of colopexy was shown by her return recently when at operation an ulcer of the posterior wall of the stomach was excised. (2) A man, aged 34, who suffered from indigestion for seven years. He had flatulence and pain three to four hours after food. Vomiting relieved pain. The stomach was atonic. An ulcer was found on the posterior wall of the lesser curvature and there was much hypertrophy of the pylorus. Half the stomach was removed as Mr. Joll was of the opinion that the ulcer would not heal with posterior gastro-enterostomy. (3) Specimen showing a perforated gastric ulcer from a girl, aged 12 years, who died soon after admission. (4) A patient who had an operation two years ago for appendicitis. As he had a swelling he was operated on and a gangrenous and perforated appendix was removed; he developed a faecal fistula, now healed.

Mr. H. DAVIES showed: (1) A man, aged 78, from whom he removed a tumour, the size of a foetal head, from the biceps cruris. The tumour was painful, adherent to the skin but not to the bone, and proved to be a spindle-celled sarcoma. (2) A man with a Charcot knee-joint of sudden onset. There were loss of knee-jerks and Argyll Robertson pupils. He was treated by a walking calliper.

Dr. M. DAVIDSON showed: (1) A young man, a stoker, with wasting of the muscles supplied by the median and ulnar nerves of the left hand. He was otherwise healthy. There was no cervical rib nor evidence of progressive muscular atrophy. (2) A boy suffering from bronchiectasis and paresis of the orbicularis oris muscle and wasting of shoulder girdle muscles. (3) A woman with fibrosis of both lungs, who developed enlargements of the ends of the bones, fingers, wrists, and ankles.

Dr. H. PRITCHARD exhibited specimens from a case of infective endocarditis showing vegetations and infarcts in the spleen. The man had no fever and only complained of fainting attacks. Mitral regurgitation was present.

Reviews and Notices of Books.

ST. ANDREWS INSTITUTE.

Reports of the St. Andrews Institute for Clinical Research. Vol. II. London: Humphrey Milford, Oxford University Press. 1924. Pp. 190. 10s. 6d.

EVEN the busiest practitioner should spare the time necessary to study reports issued by this Institute. In the first place the workers there have his interest particularly at heart and are concerned to produce work whose clinical application shall follow as closely as possible behind its academic interest, and in the second place they have the habit of putting forward their results in an attractive way. The second volume maintains the high standard of the first; it contains ten papers of great interest on physiologico-clinical matters, centring mainly around the problems of the reflex arc and cellular action.

The late Sir James Mackenzie, until recently Hon. Director, was responsible for the first two papers, the substance of which has been published. In the first of these the various forms of irregular pulse are considered, sphygmographic and venous tracings being shown parallel with diagrams which display the processes at work in the heart substance. In the second there is a further elaboration of the principle enunciated in the first volume of "Reports"—viz., that the great majority of the symptoms of disease are of the nature of a disturbance of a reflex process. In the succeeding paper Dr. A. Walker briefly cites two cases of tremor and fibrillation in muscle supporting the view that nerves of supply exert control on the muscles innervated.

Most practitioners have learned by now that the old academic signs of heart failure are not the best clinical tests of the efficiency of myocardium. Dr. James Orr, in a previously unpublished paper entitled "Cardiac Pain in its Relation to the Response to Muscular Effort," discourses further on this subject. The criterion of inefficiency is the prematurity of onset of symptoms of over-taxation, applied to the daily round and common task, not to any standard test or special exercises. Dr. Orr quotes, with excellent illustrations, 13 cases showing that an impaired heart which is able to maintain an adequate blood-supply to the body manifests its condition by pain, while breathlessness supervenes when the output is inadequate. Prof. P. T. Herring writes on the Regulating and Reflex Processes, and reviews the present opinions of the Institute with regard to the general principles underlying reflex action and their application to abnormal functioning. He also reprints his paper on the Law of Fluctuation, previously published in *Brain*, in which it is suggested that the multiplication of receptors and branches of the neurone at the periphery and of dendrites at the synapse is due to the need to supply relays of the readily fatigable units to serve the indefatigable nerve fibre. He also illustrates the conception of relays of fibres, working alternately under the "all or nothing" law, in continuously acting muscles, such as the diaphragm and heart.

Next Prof. David Waterston records an investigation into the sensory activities of the skin for touch and temperature, as a result of which he concludes that deformation of the skin is the effective stimulus for touch sensation, the epithelial cells themselves acting as the receptors. The baffling variations in temperature-spots noted by other observers are explained by the law of fluctuation, only a few spots being active at any one time, as, being readily fatigued, they are soon replaced by others not previously active. Drs. J. H. P. Paton and A. Rowand publish a report on 15 radiograms of normal infants' chests in which they found considerable shadowing around and radiating from the roof of the lung, probably due to blood-vessels, and much variation in the shape of the heart shadow. This is another reminder of the necessity for knowing more about

the normal before we begin to dogmatise on the pathological in X ray work. Dr. Paton also contributes a clinical study of a mild influenza epidemic in the same school as that which formed the subject of his paper in the first volume of reports. He concludes that the incubation period is normally 48 hours and the period of infectivity at least six days, that acquired immunity is of short duration, and that prophylactic vaccination does not seem likely to be of value.

The concluding paper in the volume is a reprint of the observations of Prof. Herring and Dr. F. G. Macnaughton on the lymphatic system, with special reference to tuberculosis. In the introduction the references to previous appearance of certain of the contributions in medical journals have not been checked.

DYSPEPSIA: ITS RELATION AND TREATMENT.

Second edition, revised. By W. SOLTAU FENWICK, M.D., B.S. Lond., late Physician to the Evelina Hospital for Sick Children. London: W. B. Saunders Company, Ltd. 1924. Pp. 515. 24s.

THIS book cannot be called representative of the views held by modern observers of the phenomena of dyspepsia; indeed, the author ignores recent research completely, his general views diverging from those which to-day are accepted either as authoritative or as replacing former ones. But there is, we hasten to say, no pretence whatever in the volume to cover grounds unsurveyed by the author. Of the mass of references given in the bibliography but a small proportion has reference to work published during the present century, and as far as we have been able to see there are only four allusions to work which was done during the last 15 years, while of these three concern contributions from the author himself. There is no reference we think to the work of A. J. Carlson, B. B. Crohn, M. E. Rehfuess, J. C. Roux, A. Alvarez, C. Moutier, P. Le Noir, A. F. Hurst, C. Bolton, T. I. Bennett, or D. Hunter, and only a few of the many distinguished surgeons whose activity all over the world has thrown a flood of light on the problems of dyspepsia are mentioned. The author does not attempt to give the impression that he has sorted and evaluated this mass of modern work, and some doubt must arise as to the meaning of the statement that this, the second edition of the treatise, is revised. The first edition was published 14 or 15 years ago, and our review of it indicated that it contained helpful advice both in classification and therapeutics, and how could it be otherwise considering the author's experience? But a re-issue taking little or no account of the progress that has taken place in the interval following a first imprint requires more justification than can be found in the survival of popularity. We doubt if Dr. Fenwick has been wise to sanction the second edition without bringing the work more up to date either personally or through collaboration.

CHEMICAL DYNAMICS OF LIFE PHENOMENA.

By Prof. OTTO MEYERHOF, Kiel. London: J. B. Lippincott Company. 1924. Pp. 110. 12s. 6d.

THIS little book consists of five separate lectures by Prof. Meyerhof, published together as one of the monographs on experimental biology issued under the general editorship of Jacques Loeb, T. H. Morgan, and W. J. V. Osterhout. The first lecture, entitled "On the Physico-chemical Mechanism of Cell Respiration," was delivered in Cambridge in the summer of 1922 and was printed in its original form in THE LANCET (1923, i., 322). The remaining lectures were delivered at several places in America, including the Rockefeller Institute of New York. In the second lecture, entitled "Autoxidations in the

Cell," the author expresses the opinion that "the more closely we study the machinery of life in the isolated cell, the clearer it becomes that the chemical and physio-chemical processes predominate in it." In support of this he reviews the evidence for the continued respiration phenomena in unfertilised sea-urchins' eggs after destruction by grinding with sand, and in other autoxidisable systems such as glutathione, and comes to the conclusion that the unsaturated linolenic acid "represents the most essential oxygen acceptor of muscle in presence of SH." The lecture ends with the statement that "only the collection of a large number of data will complete the task of tracing the oxidation mechanism in the cell back to the events of inanimate nature." The second lecture, entitled "Chemical Relations between Respiration and Fermentation," is concerned with the demonstration of the fact that the dialysable thermostable "respiratory substance" contained in boiled extract of muscle can replace the co-enzyme of yeast in restarting the fermentation of yeast, from which the co-enzyme has been removed, and consequently that the same body can serve both for respiration and for fermentation. A further link between the two processes of carbohydrate metabolism is furnished by the demonstration of the occurrence of hexose phosphate esters in both cases and the remarkable fact that arsenates which accelerate fermentation by stimulating the cleavage of hexose phosphate, also increase the respiration of muscle, presumably by the same process of stimulating the hydrolysing enzyme hexose phosphatase. From these facts it is concluded that the co-enzyme common to respiration and fermentation may be concerned in the esterification of organic compounds with phosphoric acid, whereby such compounds become more unstable or susceptible to attack; the suggestion is indeed put forward that such esterification is a preliminary to the respiratory oxidation of fats as well as of carbohydrates. The lecture concludes with the significant remark that "it may indeed be considered a success of general physiology, and its mode of experimenting, that the chemical dynamics of a highly differentiated organ like the muscle could be partly revealed by the study of alcoholic fermentation of yeast."

The two remaining lectures on the "Transformation of Energy in Muscle" and the "Energetics of Cell Processes" form rather difficult reading and will only be appreciated by those who have some acquaintance with thermodynamical reasoning. The author expresses his indebtedness to others for the revision of the English text. This revision would appear to have been somewhat perfunctory; the style frequently betrays evidence of a too literal translation, which does not necessarily convey the exact meaning of the original.

BOOKS FOR NURSES.

Elementary Anatomy and Physiology for Nurses. Third edition. By H. CLIFFORD BARCLAY, M.D., F.R.C.S. Edin.; late Major R.A.M.C.; Examiner in Forensic Medicine, New Zealand University. London: Baillière, Tindall and Cox. 1924. Pp. 411. 12s.

THIS book is a remarkable one, its title giving no hint of its scope or worth. It is intended as an introduction for nurses to the scientific foundations of their work, and to the principles underlying the work of physicians and surgeons. The author premises that some knowledge of anatomy and physiology are essential for an intelligent comprehension of a nurse's duties, but he goes further and treats of these subjects as branches of the wider subject of biology. In his hands the result is a logical and orderly review of life, its origin, its conditions, and its meaning, commencing with the vague movements of an amoeba in search of food and ending with what are, perhaps, the equally vague efforts of the human psyche after happiness. The first half of the book is devoted to a

brief but clear sketch of human anatomy, but it is in the second half that the author really finds himself. A sketch of evolution and of the nature of protoplasm leads up to a series of short chapters on the physiology of the various organs and vital processes. This is followed by a very complete discussion on embryology in its relation to defects, one of the best chapters in the book. Last comes a series of chapters on modern aspects of psychology.

The author has succeeded in an ambitious undertaking. Writing in an easy and simple style he manages to elucidate various difficult conceptions by homely illustrations, and to carry his reader with him throughout. For the purpose for which it is intended the book could scarcely be surpassed, but it ought to appeal to an even wider circle. No better introduction to medical work could well be placed in the hands of a student, and we venture to think that there are few medical men who might not read it with profit.

Text-book for Fever Nurses. Revised edition. By GRACE H. GIFFEN DUNDAS, F.R.C.S.I., D.P.H. Camb. Edinburgh: William Bryce. 1924. Pp. 228. 4s. 6d.

THIS little book can hardly fail to be useful to fever nurses. It is divided into two parts, the first of which is devoted to anatomy and physiology and the second to the principles of fever nursing and to the characteristics of the infectious diseases. It supplies the information required by the syllabus of the Fever Nurses Association, and as the examinations have now been transferred to the General Nursing Council appendices have been added to this edition designed to meet the requirements of that body. The section on hygiene introduced with this object appears to us to be somewhat meagre; what little information is given about food stuffs and values might well be expanded in another edition. Information that the incubation periods of rubella, measles, and chicken-pox are "about a fortnight" is hardly adequate. Surely the possible limits of the incubation period in each case should be laid down with more exactness with a view to quarantine. Until the General Nursing Council has held more examinations it is difficult to know what standard is required. So far as we can judge, the fever nurse with a good knowledge of the contents of this little book should not fear the result, and many teachers may feel that the author's estimate of what a nurse should know is more reasonable than that suggested in the syllabus of the Council.

Dr. Dundas in her preface emphasises the need of careful study of the diagrams and models which all hospitals nowadays provide. Otherwise, if this opportunity were not available, the nurse would have little chance of profiting from the study of a book without illustrations. But to supplement hospital lectures and for the purpose of revision the book seems admirably adapted, and it has the advantage of being simply and clearly written.

The Care of Tuberculosis. A Treatise for Nurses, Public Health Workers, and all those who are interested in the care of the tuberculous. By J. A. MYERS, Ph.D., M.D., Assistant Professor of Preventive Medicine and Public Health, Graduate and Medical Schools, University of Minnesota. With an Introduction by RICHARD OLDING BEARD, M.D., Associate Professor of Physiology, University of Minnesota. London and Philadelphia: W. B. Saunders Company. 1924. Pp. 229. 10s.

LIKE many other authors of popular books on tuberculosis, Prof. Myers found, after teaching nurses the elements of tuberculosis, that it was desirable to summarise his teachings in a book. It seems almost inevitable that lecturing on tuberculosis for a certain number of years should culminate in this manner, and though few of the books belonging to this class

are likely to enjoy a wide circulation for this reason, among others, that they are so numerous, they are calculated to be most useful to the tuberculosis workers in the author's sphere of influence. Some of us can best acquire information by the ear, and others by the eye; and the teacher most likely to transfer his knowledge successfully to others is he who employs both means. Of the book it is necessary only to say that it gives a perfectly sound and impartial account of the most salient features of our present knowledge of tuberculosis. There are few specialists in tuberculosis whose knowledge thereof is not impaired by fads and foibles. The author may not be bereft of these afflictions, but he certainly does not impose them on his readers. In his account of artificial pneumothorax he mentions a fact, not generally known, that Dr. E. L. Trudeau, "after having suffered at intervals for nearly 40 years from pulmonary tuberculosis, was entirely relieved of symptoms from the date of the collapse of the diseased lung, two years before his death, resulting from other causes, at the age of 67 years."

ADVENTURES IN TRIPOLI.

A Doctor in the Desert. By ERNEST H. GRIFFIN, D.S.O., M.C. London: Philip Allan and Co. 1921. Pp. 298. 10s. 6d.

FEW men have greater opportunities for indulging their tastes, should these lie in the direction of travel and adventure, than the doctor. Explorers, prospectors, and hunters are always prepared to include medical men in their parties, and when the nations are at variance the demand is so great from all branches of the fighting services and their allied organisations that even the naturally stay-at-home doctors find themselves pitchforked into queer places.

Dr. Griffin, being very far from a stay-at-home, seized the opportunity offered by the Italian annexation of Tripoli. In the autumn of 1912 he took service under the British Red Crescent Society, and his book records his experiences during the months in which he served with the Turks and Arabs. Like some others who have lived among them, Dr. Griffin is full of sympathy and admiration for the Turk. He does not see him as the blood-stained monster of the Gladstonian tradition, but as a courteous and humane gentleman; and whether or no personal bias has coloured his narrative in this direction it would be well if those who allude always to the Turk as unspeakable would read of the distress caused among the Turkish officers on hearing of the atrocities committed by the invading Italian troops in the frontier Turkish villages. But in writing well of the Turks, Dr. Griffin does not fail to do justice to the way in which the present Italian Government are treating the inhabitants of the new Italian colony, which enjoys due civic and political liberties.

The many episodes of a long adventure which form the contents of this easily flowing narrative are well written as well as exciting, owing much of their interest to their diversity and the suddenness of their occurrence. And interspersed with these, with political reflections, and with detailed descriptions of medical work, we have notes on the geography, climate, and natural history of Tripolitana, which may be neither new nor profound, but which bring the scenes into the reader's eye with vividness, some good and well-selected pictures helping to the same end. When the Turks evacuated the country, Dr. Griffin remained behind to minister to the wants of the Arabs, among whom he made many close personal friends, but the closing chapters, which are among the most stirring in the book, show that his interest in Arab civilisation nearly cost him his life, and that his final escape was a hair-breadth one.

The book is one that should be read widely, for in every line it breathes that spirit of comprehension and tolerance which, if it infused the governments of

the world, would clear up many of the situations which now eventuate in war. There is one side of Dr. Griffin which would hold that such a consummation is worth all the effort that mankind can put out; and there is another side of him, equally revealed in his book, which would find a world without wars a colourless and dull affair.

JOURNALS.

JOURNAL OF PHYSIOLOGY. Vol. LIX., Nos. 4 and 5. 1924.—Twenty-four Hours' Observations on the Metabolism of Normal and Starving Subjects, by I. Cohen and E. C. Dodds. The urine of five normal men, three taking food and two starving, was examined at half-hourly intervals for 24 hours in order to determine the half-hourly variations of the urinary constituents, and if possible to assign some cause and also to determine to what extent exogenous factors operate. The majority of the blood constituents remained remarkably constant over a given period. There seems to be no material change in the urea-concentration of the blood because of changes in the level of the nitrogenous metabolism. The only blood constituent showing any marked variation is glucose. An alkaline tide is, it seems, associated with meals, and more particularly with gastric secretion. After breakfast there was a rise in the alveolar CO_2 tension, which corresponded with the secretion of HCl from the stomach, a slight rise in the pH of the urine, a fall in the A+N value, a fall in the ammonia coefficient, and a rise in the nitrogen coefficient. These changes were all reversed a little later when pancreatic secretion began to flow. This evidence supports very strongly the original contention of Bence Jones. The evidence of acidosis was present even after so short a period of starvation as 24 hours. The marked variations in the urinary diastase could not be attributed to meals, since variations occurred in the starvation controls. The urinary diastase content would seem to be quite independent of the intake of food. All the results emphasise the uselessness of analysing isolated specimens of urine, and of basing conclusions on short-time observations without rigid starvation controls.—Influence of CO_2 on the Absorption of Alcohol by the Gastric Mucosa, by Nora Edkins and Margaret M. Murray.—Influence of the Ovary on Pituitary Secretion, by W. E. Dixon and F. H. A. Marshall. (See Annotation, p. 243.)—Influence of Insulin on the Blood-sugar in the Heart-Lung Preparation, by F. Plattner. The experiments were made on dogs, 1 g. of glucose being added to the circulating blood. On the subsequent addition of insulin to the blood there is no increase in the rate of disappearance of blood-sugar so long as the heart-rate is not increased, but if the heart-rate increases after the addition of insulin the sugar disappearance is found to increase in the same ratio.—Mechanism of the Splenic Reaction to General CO Poisoning, by S. de Boer and D. C. Carroll. In animals poisoned with CO there are differences in the COHb content between the hæmoglobin of the splenic pulp and the arterial blood. The experiments were made on anaesthetised cats with a mixture of air and CO of known composition, and the B.P. and splenic volume recorded. In cats poisoned with CO the spleen volume decreases, the B.P. falls if the rate of poisoning is rapid, and either falls slightly or remains constant if the CO is slowly absorbed. The mechanism is very sensitive and responds to as low a percentage of COHb in the blood as 8 per cent. The decrease in volume of the spleen is independent of the B.P. changes, and is due to an active contraction of the spleen musculature. CO poisoning does not cause any vaso-constriction in the spleen. The excised surviving spleen does not contract, but dilates, when poisoned with CO, an effect due to oxygen-want. The spleen does not contract in response to general CO poisoning of the animal when it is removed from nervous connexion

with the body, either by nicotine poisoning or by decentralisation, although in each case the spleen itself is poisoned with CO. The contraction is not due to an effect on the adrenals or on the pituitary body. The spleen perfused with oxygenated Ringer but in normal nervous connexion with the body contracts when the animal is poisoned with CO. The spleen of the decerebrate cat contracts in response to general CO poisoning. It is concluded that the spleen contracts owing to the effect of CO in producing an oxygen-want in the spinal cord, and it is suggested that a function of the splenic contraction is to expel unpoisoned red cells into the blood, and so reduce the proportion of COHb to HbO_2 in the general circulation.—The Action of Pituitrin on the Splenic Volume. The same authors find that pituitrin does not cause a contraction of the excised spleen. The decrease in splenic volume which follows the intravenous injection of pituitrin in the intact animal is due to vaso-constriction. Pituitrin is without action on the plain muscle of the spleen.—Migration of Ova in the Rabbit, by A. S. Parkes. Ovariectomy on one side and salpingectomy on the other side make breeding conditional upon external migration of ova. Six rabbits operated on in this manner were successfully mated for three to four months without becoming pregnant, and showed no signs of pregnancy when killed. Ovarian excision and salpingectomy on the same side was found not to prevent pregnancy. It is concluded that external migration of ova is very rare.—Effect of Certain Changes in the Perfusate upon the Isolated Auricles of the Rabbit, by E. Cowles Andrus.—The Heart Output During Respiratory Obstruction, by A. St. G. Huggett. The method employed on intact urethanised cats is described. The minute-volume and stroke-volume were measured during inspiratory, expiratory, and combined expiratory and inspiration obstruction (against a measured water pressure). Inspiratory obstruction increases the minute- and stroke-volumes of the heart. It causes an increase in oxygen consumption and a fall in the utilisation. Expiratory obstruction causes the exact reverse in all respects. Combined inspiratory and expiratory obstruction causes a decrease in the oxygen consumption and in the minute- and stroke-volumes. The oxygen utilisation is increased. The pulse-rate undergoes only a slight change. The circulation-rate is approximately proportional to the output per beat.—Action of Adrenalin on the Central Nervous System, by A. St. G. Huggett and J. Mellanby.—Latent Glandular Hermaphroditism: New "Unbolting" Experiments, by Alexander Lipschütz. The author has shown that the hormonal effect of an ovarian graft in the male is favoured when the testicular mass is reduced experimentally. With intra-testicular or intra-renal ovarian transplantation, in all cases in which one testicle was removed, a feminine hormonal effect was produced and the time of latency shortened. There was never a feminine hormonal effect when both testicles remained untouched in the body of the engrafted animal. These results give support to the view that there is an antagonism between the graft and the sex glands *in situ*. In a male guinea-pig with one ovary engrafted, both testicles being retained, the results were negative for seven weeks. Then both testicles were removed, and in less than ten days the feminine hormonal effect on the teats became manifest. It is like an obstacle or bolt being removed which so far inhibited the manifestation of the feminine hormonal effect. This is why the author uses the word "unbolting" to such experiments. The author regards those cases in which an ovarian graft "takes"—i.e., becomes implanted and vascularised—in the male, notwithstanding the presence of both testicles, as "latent glandular hermaphrodites," in which the hermaphroditism becomes somatically manifest after the antagonistic influence is suppressed. The simplest method of rendering manifest somatically the intersexual condition of similar cases is testicular castration (the "unbolting" experiment).

THE LANCET.

LONDON: SATURDAY, JANUARY 31, 1925.

THE ROYAL COMMISSION ON NATIONAL HEALTH INSURANCE.

MEMBERS of the medical profession throughout the country have been invited to consider during the present month the draft of the memorandum proposed to be placed before the Royal Commission on National Health Insurance by the appropriate Committee of the British Medical Association. This memorandum was summarised in our issue of Jan. 10th. It is evident from its scope that questions of far-reaching importance to the whole profession will come under the review of the Commission. It would be an idle and inappropriate figure of speech to say that the medical profession is at the parting of the ways. This was true in 1912, when the decision was taken to accept the national health insurance system on trial, and a majority of the general practitioners of this country were, in effect, enlisted in a vast new branch of public service. A system which for 13 years has provided medical treatment for practically the whole wage-earning population, now numbering 15 millions, and which, as appears from the evidence, enrols 12,000 out of the 18,000 general practitioners engaged in actual practice, has clearly come to stay.

The vexed question of remuneration which has unfortunately occupied far too prominent a place in the picture in the past is, for the time being, at rest, although new manifestations of it may arise if some of the developments discussed in the British Medical Association's memorandum should materialise. It is these developments to which, at their local meetings, the members of the profession have been applying their minds, and we think it wise that those who are not engaged in panel practice should have been invited to consider with their colleagues the whole of the vital questions of policy raised in the memorandum. These embrace such enormously important matters as the desirability of including the dependants of insured persons within the insurance scheme, the future position of patients now under the Poor-law, the question of the extension of the scope of the present medical scheme so as to include specialist and consultant services, and the possible disappearance of insurance committees and Poor-law guardians and the transfer of their functions to a new local health authority. Before the views put forward by these local gatherings of the profession are considered in council by a central body of representatives in March, we hope to lay before our readers a summary of the evidence given on behalf of the Minister of Health and the Scottish Board of Health as to what the insurance scheme—and not merely the medical benefit provisions—really comprises and how it has worked. This evidence gives us for the first time a comprehensive picture of the insurance system which can be summarised in a fairly short compass, and we get a considered and responsible expression of opinion of the working of that system. The official view as to possible developments will, it is understood, come later when the evidence of the medical profession and of the societies and other bodies working under the Act has been heard by the Commission.

We hope, following the first instalment of evidence in this issue which deals with the general scope of National Health Insurance, to give rather more fully, in perhaps three or four instalments, the official evidence as to the medical benefit system. This will be followed by a concise account of the evidence of the more important approved societies, of special points of interest in the working of the scheme in Scotland, and by a short review of the financial structure of the Insurance Acts and of the cost of their administration. In this way, while avoiding matters of detail too remote from their daily work to be of interest to medical practitioners, we shall hope to have placed our readers in possession of the more interesting features of the whole of the evidence given by the time the witnesses on behalf of the profession appear before the Commission in April. Thereafter each instalment of evidence will be summarised as it appears.

THE ACTION OF GOLD ON TUBERCULOUS TISSUES.

THE efforts to enlist gold in the therapy of tuberculosis have extended over many years. Hopeful results have been claimed by certain observers and others have been baffled and discouraged by the sharp reaction that has followed the administration of this metal. During the last year there have been persistent rumours from Denmark that the long awaited specific has been found and the full account of the preparation of gold synthesised by Prof. HOLGER MOLLGAARD has been eagerly looked for. His recently published book¹ sets out at some length the observations on which his claim is based. Sanoerysin, a white crystalline solid originally prepared in 1845 by FORDOS and GÉLIS, is a double thiosulphate of sodium and gold with the formula $3\text{Na}_2\text{S}_2\text{O}_3 \cdot \text{Au}_2\text{S}_2\text{O}_3 \cdot 4\text{H}_2\text{O}$. By the original method only some 15 per cent. of the gold employed emerged in the finished product, but Dr. MOLLGAARD and his collaborators speak of a new synthesis which utilises 95 per cent. of the gold and gives a pure product after a single crystallisation. The right of producing this compound, registered under the name of "Sanoerysin," has been vested in the Danish Chemo-Therapeutic Company, of Copenhagen, and it will then be supplied, as we learn from the *Northern News Service*, to hospitals either directly or through some special institutions nominated by the Government. It is unfortunate that Dr. MOLLGAARD gives no indication in his book how the synthesis is achieved, for he cannot be willing for others to use an expensive and inferior method of synthesis when he knows of a better.

The chemical and physical properties of sanoerysin are dealt with in the book in great detail. One important property of the substance is that it does not ionise into true Au ions; metallic gold is only found on slow oxidation, and the authors believe that this process, if it were to take place in the body, should be of therapeutic value. The next section is devoted to what are called the "bacteriostrophic" properties of sanoerysin. Sanoerysin in dilution of

¹ Chemotherapy of Tuberculosis: Experimental Foundation and Preliminary Clinical Results. In collaboration with Prof. Dr. V. Bie, Blegdams Hospital, Copenhagen; Dr. O. Chievitz, Finsens Lysinstut, Copenhagen; Dr. J. Gravesen, Vejlefiords Sanatorium, Vejle; Dr. G. E. Permin, Frederiksberg Hospital, Copenhagen; Dr. K. Secher, Bispebjerg Hospital, Copenhagen; Dr. Strandgaard, Boserup Sanatorium, Roskilde; Dr. C. H. Würtzen, Øresunds Hospital, Copenhagen. By Holger Mollgaard, Prof. of Physiology, Physician, Royal Veterinary and Agricultural College, Copenhagen. Nyt Nordisk Forlag: Arnold Busck, Copenhagen. 1924. Pp. 419 and many plates. 25s.

one in a million and under is found to inhibit the growth of the tubercle bacillus in vitro, but the proof of actual bactericidal properties is rather vague. After washing inhibited cultures (method not given, nor any proofs that all the heavy metals had been removed) growth did not take place in bouillon, but if the cultures were injected into guinea-pigs, generalised tuberculosis developed. The further guinea-pig experiments do not carry us very far. The method adopted was to inject living culture and immediately to follow this by an injection of sanocrysin at the same site. The pigs were thereby protected from generalised tuberculosis in the majority of cases. The authors themselves evidently realise the fallacies attending this method, since they state (p. 31): "Owing to this fact and further because preventive experiments, where the therapeutical stuff is injected direct into the infected place, are of minor interest, many other chemical stuffs probably being able to kill tubercle bacilli when directly applicated on them. I have made only few experiments of this kind." The next chapter is devoted to the effect of sanocrysin on non-tuberculous animals. The general conclusion arrived at is that it is non-toxic in doses of 0.2 g. per kilo of body-weight. Slight albuminuria may result. Renal function was judged by the excretion of administered iodine, an unfamiliar test in this country. If the test animal has any infection other than tuberculosis, the administration of sanocrysin is often followed by marked renal change; the authors remark that for the present "Sanocrysin should never be injected into organisms affected with other infectious diseases than tuberculosis." This observation, if confirmed, would restrict the use of the remedy considerably, since secondary infections in tuberculosis are extremely common. The authors then deal with the results of sanocrysin injections upon tuberculous animals. To put it briefly, these were followed by shock and rash, similar to tuberculin shock, which could be prevented, in most cases, by the administration of serum from a tuberculous animal. The authors assume that these results are due to the bactericidal effect of the sanocrysin, endotoxin being liberated, but other explanations might be advanced. Tuberculin shock may be produced, for example, by purely physical means, such as massage and exercise, and the sanocrysin might act by merely damaging the tissues and washing out bacteria and toxins. LYDIA M. DE WITT, writing² of the significance of these tuberculin reactions following the injection of gold salts, says: "From all experiments, we may conclude that the use of gold salts is not without danger. When active, the actions seem associated with marked hyperæmia and possible hæmorrhage in the neighbourhood of the tubercles." The most hopeful experiments recorded by Dr. MOLLGAARD are those with calves which were infected by intravenous injection of cultures, one animal being selected as a control and the remainder being treated with sanocrysin. The latter failed to develop tuberculosis, whilst the sole control died.

The literature of gold therapy being what it is, it is hardly surprising to find Dr. MOLLGAARD'S historical outline incomplete in some particulars. Thus there is no reference to the work of J. B. WHITE,³ who used a double chloride of sodium and gold, together with manganese chloride, and described promising clinical results, nor to that of MAYER,⁴ and many other workers, such as BETTMANN, JUNKER, POOR, and

GEBER, who have made similar investigations. Perhaps the most serious omission is that of the important paper by DE WITT, CADWELL, and LEAVELL,⁵ who studied the effect upon tuberculous animals of gold administered by mouth, intravenously or subcutaneously. They controlled their experiments by analysis of the tissues, and found that there was more gold in the tuberculous areas. Later DE WITT and SHERMAN extended these observations and their paper contains the following highly-important statements: "The stimulation of growth of tubercle bacilli by solutions of gold too dilute to kill or to inhibit is an important consideration in treatment, since it is difficult to keep the concentrate of gold in the animal body at or above the point required for inhibition." It may be that Dr. MOLLGAARD and his collaborators have not given full consideration to the case against gold therapy, and it is therefore the more disappointing that the product was not passed on at an earlier stage to other experimental workers for trial and confirmation. We have not been considering here the clinical trial of the remedy, with which more than half of the book deals. Clinical trial in tuberculosis, as experience has shown, is a ticklish affair.

SIR JAMES MACKENZIE.

THE death of Sir JAMES MACKENZIE removes from the ranks of medicine one of its greatest figures, one of the men who make medical history, and who, while accomplishing much themselves, provide a firm platform from which future researches can be carried forward. He regarded his work mainly as an illustration of what the well-equipped general practitioner of the future might do, and was never tired of pointing out what a mine of knowledge was here left unquarried. At a time when he was a recognised authority all over the world on the manifestations of heart disease, their significance, and their treatment, he acclaimed himself as a development of the general practitioner, inasmuch as all his working life up to that date had been done in general practice; and looking back at that work he would express his belief that to the men in general practice the whole field for future discovery was open. His own history supported the force of his words. His results were the direct outcome of the minute observation of groups of patients under his personal care in circumstances where their conditions could be followed up, and where, as analogous symptoms appeared, definite research along indicated lines could be made. The first subject to which he would direct his attention while taking these exhaustive notes was pain, and his investigation into the character of pain in a large number of cases of visceral disease compelled him to differ from accepted views as to the possibility of defining precise superficial areas of altered sensation. He used all the chances offered by a mixed general practice to look below accepted knowledge, which he found confessedly unable to explain many symptoms or to suggest remedies in many circumstances; and with the splendid intention of setting such a condition of things right to some extent and in some direction he embarked upon an intensive study of cardiac disease. How his recognition and analysis of cardiac irregularities led in time to fundamental changes in diagnosis, prognosis, and treatment is indicated in our obituary notice, the last phase of his labours being sympathetically delineated through his collaborators. To the vast general deductions that characterised this phase no summary would do justice at the present moment; but to the works that he accomplished the highest acclaim is due. Mackenzie was one of the small group of men whose individual labours have revolutionised fundamental medical views.

Annotations.

"Ne quid nimis."

VITAL STATISTICS FOR 1924.

THE Registrar-General has issued a provisional statement of the figures for birth-rate, death-rate, and infantile mortality during the year 1924.

	Birth-rate.	Death-rate.	Infant mortality-rate.
England and Wales	18.8	12.2	75
105 county boroughs and great towns, including London	19.3	12.3	80
157 smaller towns	18.9	11.2	71
London	18.6	12.0	69

The smaller towns are those with an estimated population in 1921 of 20,000-50,000. The (crude) death-rate for England and Wales relates to the whole population, but that for London and the groups of towns to the civilian population only. The birth- and infantile mortality-rates for London have been provisionally corrected for transfers.

The Registrar-General remarks that the birth-rate of England and Wales as a whole is the lowest recorded except during the war years 1917-19. The death-rates are all appreciably higher than last year. These provisional figures, which are not likely to require substantial modification, have been issued for the information of medical officers of health.

THE CLAIMS OF THE DEFECTIVE CHILD.

ARREARS in the educational provision for defectives are serious. At the present time the accommodation available in special schools is sufficient for only 41,000 out of the 150,000 blind, deaf, physically and mentally defective, and epileptic children in England and Wales. More than half the day-school places are in London, and many education authorities do next to nothing for their unfortunates. The arrears of a decade cannot, of course, be made up in a day, but the Board of Education is pressing¹ local authorities to consider carefully which class of child shall have priority. The medical branch of the board would very sensibly give precedence to the claims of the blind and deaf. It is disconcerting to learn from Sir George Newman's report for 1923 that in 208 areas alone 281 totally blind and 484 totally deaf children were either attending ordinary schools in which they could obviously derive no benefit or were getting no teaching at all. Irreparable damage to mind, character, and power of acquiring technical skill follows such neglect in childhood, and the Board's patience is at last becoming exhausted, for, runs the circular, "the Board will not be prepared much longer to regard any authority as reasonably complying with the Education Act, 1921, unless all blind and deaf children in the area are properly ascertained and provided for." Except in large towns with at least 40,000 children on the rolls, day classes are impracticable and more institutions are needed. It is important that these should be well distributed over the country, as there are valid objections to sending young children great distances from home and much of the existing accommodation is for this reason wasted.

In discussing the position of the "physically defective" child, who in practice is usually a cripple, the Board realises that the most effective measures can be taken outside the school. A good orthopaedic scheme covering town and country districts in an area will, it is pointed out, cut off the supply of cripples at the source and will largely obviate the need for the expensive special schools of the older type. Such schemes are simple and inexpensive to run and in several areas they have already revolutionised the

prospects of the child with crippling disease or deformity. It is still possible, however, to find a P.D. school complete with costly ambulance service, and hardly a cripple child on the roll under surgical treatment or in a splint. The Board does well to guard against the reproduction of such anomalies. For the "mentally defective" child, on the other hand, preventive measures are not available and their education remains a problem as "costly as it is difficult." About 28,000 are now unprovided for. The special education they need must be given in small classes by specially trained teachers or it is not worth giving. Nothing is more certain, however, that such children if neglected in early life take their revenge on society later by a social inefficiency which expresses itself in pauperism, crime, and vice. It is suggested by the Board that even where special education cannot for various reasons be provided, an education authority should at once take certain inexpensive steps which are the foundations for any efficient scheme. The number of defective children should be correctly ascertained, such as cannot be accommodated in special schools should be supervised by skilled visitors trained to advise and help parents; and at school-leaving age such children as are likely to need permanent care and control should be notified to the Mental Deficiency Committee. Like the other schemes outlined in the circular, these measures, though admittedly incomplete, should add materially to the happiness and security of these unfortunate children and of their families.

SURGICAL TREATMENT OF PARALYTIC DEFORMITIES OF THE FOOT.

WRITING on this subject in the *American Journal of Surgery* for December, 1924, Dr. Leo Mayer, of New York, sums up usefully the history of tendon-transplantation and other procedures intended to correct the deformities and disabilities of infantile paralysis. He describes with commendable fullness the details of the operations which he himself has been accustomed to perform, details which, though they may seem trivial, make all the difference between functional success and failure. For, though the operation would may have healed readily and the transplanted tendons may be firmly attached at their new insertions, the object of the operation will not be secured if the direction of action of each transferred tendon has not had due consideration, or if there are adhesions between it and adjacent structures. Dr. Mayer describes the operations upon bone, which he has found necessary in the more severe and resistant deformities, with or without concomitant tendon-transfer. He gives some good reasons for preferring the measures which he describes in cases of talipes calcaneus, to the operation devised by Royal Whitman, which has the disadvantage, in a unilateral case, of still further shortening an already short limb.

FACIAL SURGERY.

Two books¹ have recently appeared on cosmetic surgery. The one deals with surgical trivialities, little alterations in the form of lips or eyelids which might appeal to a woman of fashion or of vanity. The other plunges straight away into the most ghastly injuries that even civilised warfare has been able to achieve, and indeed it is in the late war that it found its origin. Yet it is common knowledge that the dimensions of a defect bear no relation to its effect upon the patient, and that to a woman with nothing but herself to think of a slight droop of an eyelid may seem as terrible as the loss of half his face to a healthy man. It is, indeed, in its application to the

¹ Special Schools for Defective Children. Circular 1349 to Local Education Authorities, Jan. 12th, 1925.

¹ Facial Surgery. By H. P. Pickerill, C.B.E., M.D., M.S., Lieut.-Colonel, N.Z.M.C., Surgeon-in-Charge of Facial and Jaw Department, Duncedin Hospital; Membre d'Honneur Société Belge de Stomatologie; late Surgeon-in-Charge of the New Zealand Section, Queen Mary's Hospital, Sidcup. Edinburgh: E. and S. Livingstone, 1924. Pp. 162. 21s. Cosmetic Surgery. By Charles Conrad Miller, M.D. Philadelphia: Davis Company, 1924. Pp. 263. 8s.

minor defects of civil life that the work of the plastic surgeon of the war finds its outlet at the present day, and indeed some of these defects produce really serious deformity. Mr. Pickerill was one of the group of surgeons who worked in the later years of the war at the great hospital established by Queen Mary at Sidcup for the treatment of facial injuries, and he can claim his share in the advances made by the combined efforts of that group. The first part of his book deals with the methods which were there elaborated, and by many examples he illustrates their application to facial injuries of every degree and character. Excellent photographs and neat line drawings enable the reader to follow the operative steps, often very complex, by which the injuries were repaired and to appreciate the excellence of the results. The remainder of the book demonstrates the application of the methods to the more moderate requirements of civil life, such as the filling of defects due to the removal of growths, to lupus, syphilis, and other conditions. In a chapter on deformities he deals with hare-lip and cleft palate, and describes a new and interesting method of dealing with the latter condition. Though we may not always agree entirely with the methods advocated, the book is full of interest and suggestions, and we can strongly recommend it to the notice of all surgeons who aspire to deal with facial deformities. Dr. Miller deals solely with the lighter side of plastic surgery; his book is of real value in that it calls the attention of surgeons to the possibilities of a branch they are apt to neglect. The operations described are all done under local anaesthesia and they range between the correction of a hump nose in a bruiser and the dainty formation of a dimple in a lady of fashion. It is unfortunate that no photos of actual cases are given to enable us to compare the lustre of these reconstructed gems with that of the genuine article. But the methods advocated are logical and sound in conception, and although they seem very simple anyone who is skilled in the art will appreciate the nice judgment they require. The surgery of beauty is a risky field for the amateur, but those who master its principles will find its problems not without interest.

ARSENIC IN THE URINE.

IN the current issue of the *Analyst* an important paper appears by Mr. H. E. Cox, M.Sc., Ph.D., on the determination of small quantities of arsenic, and on the occurrence of this element in normal urine and in fish. The stimulus to Dr. Cox's work was given by the work of the Commission on Arsenic Poisoning in Sweden, whose report appeared a year ago (THE LANCET, 1923, ii., 531). Much of the value of both rests on details of experimental technique; both the Swedish Commission and Dr. Cox stress the importance of the complete destruction of all the organic matter present in the substance being assayed for arsenic, as fully as is done in the Kjeldahl process of estimating total nitrogen. The subsequent complete removal of nitric acid and nitric oxides is also essential for, unlike the Kjeldahl process, the addition of nitric acid is part of the method, the excess being removed by adding a considerable quantity of ammonium oxalate. It is stated that unless the organic matter is thus destroyed the arsenic is not rendered soluble or left in a form suitable for estimation by one of the well-known methods. While, no doubt, this is true, it must be borne in mind that a far larger quantity of reagents must be employed in each such test than is required for the older process where the organic matter is only partly destroyed. Dr. Cox states in one place that he used arsenic-free reagents and in another that his blank control always showed the same minimal figure which was constant. The term "arsenic-free" as applied to reagents is relative; it is impossible to obtain reagents literally free from arsenic. Many reputable chemical manufacturers label their strong acids "arsenic less than 0.1 part per million," and many samples of reagents

contain less than this quantity. It becomes necessary, therefore, to exercise caution, especially regarding some of the smaller values before accepting the conclusions either of Dr. Cox or of the Swedish Commission, especially as according to the former the amounts taken of his reagents contained in some cases as much arsenic as the amount of urine taken for experiment contained. This was, of course, allowed for, but it cannot be regarded as satisfactory when dealing with very minute amounts. The following tables give the Swedish figures for urine and fish:—

Urine.

One hundred persons on a known hospital diet:—

As ₂ O ₃ mg. per litre.	Percentage of cases.	As ₂ O ₃ mg. per litre.	Percentage of cases.
0.00-0.01	21.1	0.10-0.20	21.1
0.01-0.03	18.4	0.20-0.30	2.6
0.04-0.06	23.7	0.30-0.70	5.2
0.06-0.09	7.9		

Dr. Cox expresses the opinion that the arsenic figures given are rather too high.

Fish.

British—	Mg. of As ₂ O ₃ per 100 g. of fish.	British—	Mg. of As ₂ O ₃ per 100 g. of fish.
Whiting	0.04	Haddock	0.06
Plaice	0.14-0.30	Brill	0.03
Sole	0.03	Mackerel	0.05
Hake	0.03	Halibut	0.03
Herring	0.03	Turbot	0.05
Cod	0.05		
Swedish—		Swedish—	
Mackerel	0.01	Plaice	0.05-0.09
Herring	0.03	Sole	0.01
Haddock	0.02	Cod	0.04

Dr. Cox's figures for urine (hospital patients):—

16 cases	Mg. of As ₂ O ₃ per litre.	Mg. of As ₂ O ₃ per day.
	0.00-0.09	0.00-0.09
Four cases on fish diet—		
1.	0.10	0.18
2.	0.25	0.19
3.	0.58	0.61
4.	0.33	—

It will be seen that in the main the figures are in agreement, and the interesting point emerges that some of Dr. Cox's higher values for urine were in patients partaking of a fish diet. This fact may be of importance in regard to patients recovering from a possible sublethal dose of arsenic, as, of course, fish is a common diet of convalescence. It must also be remembered that the B.P., 1914, arsenic limit of various drugs varies from 0.2 to 10 parts of arsenic per million, with certain exceptions. Although high-grade chemicals rarely, if ever, reach these limits, many hospitals for reasons of economy use less pure chemicals, adopting the B.P. as their standard. Certain observers in the past have found traces of arsenic frequently in the urine of healthy persons, but others have often examined urines taking for estimation far larger quantities of urine than Dr. Cox took, and have obtained negative results. No doubt this failure might be attributed to the want of employment of Dr. Cox's technique. The present position is one of difficulty. It may be fairly accepted that arsenic is present in the urine far more frequently than was previously suspected, but not, we venture to think, quite as frequently as Dr. Cox maintains. From the medico-legal standpoint his work will require some consideration, but where a possible fatal dose of arsenic has been administered the amount found in the urine and faeces within a reasonable time of the dose would be far greater than the amount found in the fish diet cases, and would be associated with clinical symptoms. It is, therefore, not very likely that Dr. Cox's discoveries will seriously complicate the medico-legal issue. As an example of the rate of excretion of arsenic we understand that, by the old method, arsenic has been found in the urine and faeces of a patient for 14 days after the administration of liq. arsenicalis Miii. t.d.s. for one day (9 minims in all). By the fifteenth day it had disappeared and none was detected during the next two days.

SOUTH AFRICAN MINE DUST.

It is some years since the pioneer methods of dust-sampling as practised in the South African gold mines first attracted and held the attention of those interested in the study of silicosis. There are two methods concerned—namely, the gravimetric (or sugar-tube) method in which dust is weighed, and the so-called konimetric (Gr. *kónis*, dust) method in which the particles are counted with the aid of a microscope. General confidence in these methods has apparently diminished because the gravimetric returns, though reliable within their limitations, did not afford the necessary information; while lack of correlation between the konimetric returns of different observers or groups of observers, and their not infrequent lack of correlation with simultaneous gravimetric returns, has shaken confidence in this the alternative method. In a well-illustrated monograph,¹ which has recently come into our hands, a group of workers at the South African Institute for Medical Research review the position as it appears to them on the Witwatersrand, and present their most recent technique for standard routine sampling in the mines whilst actually at work.

Dr. Mavrogordato states that, in 1911, 25 per cent. of employees contracted silicosis, developing the symptoms within a couple of years; in 1917 only about 6 per cent. of workers were affected by the disease, and they were now taking from nine to ten years to develop the symptoms; and in 1922 less than 3.5 per cent. of the men employed were contracting silicosis, and they required from nine to ten years to develop symptoms. He also points out that the results of "dust surveys" in 1915 registered by the gravimetric method an average of 4.9 mg. of dust per cubic metre of air, whereas in 1919 the average had fallen to 2.9 and in 1923 it was only 1.3. It is obvious, therefore, that the diminution in the amount of silicosis has gone hand in hand with the diminution in the dust content of the air, as measured by their methods, and this fact should give confidence in the value and reliability of these methods. He is very careful to make clear that the routine methods at present in practice, although the best available under actual working conditions in the mines, are by no means perfect, and there are still difficulties to be surmounted. Dr. Mavrogordato prefers the konimetric method for routine sampling to the gravimetric method because the former is less trouble, demands less skill and less equipment, while at the same time it gives more prompt returns. In taking the sample of dust the konimeter (Kotzé or circular pattern) causes a small volume (5-10 c.cm.) of air to pass at a high and definite velocity, through a standard narrow jet, and to impinge upon a glass slide covered with adhesive material (glycerine jelly). The dust particles are counted with a microscope giving a magnification of $\times 120$, using a fixed and standard illumination, and also a special arrangement of stop and condenser to obtain a definite dark-ground illumination so as to evade the ultra-microscopic effect as far as possible, since ultra-microscopic particles of silica are either innocuous or non-existent; large particles of silica are also comparatively unimportant, the particles producing silicosis measuring from 5μ - 0.25μ . When it is the latter alone that would have to be counted by a perfect method, the difficulties in the way of introducing such a method are obvious. Nevertheless the standard routine described is considered to yield sufficiently approximate returns with a minimum demand on the operator. The drawback of the method is that it measures the total air-borne particles but not necessarily silica; the complications introduced by carbon, by fog, and by water-soluble

particles have also to be considered, and some measures to overcome these troubles are described. Dr. Mavrogordato and his colleagues do not rest satisfied with the present routine methods, and they hope to obtain the help of the dust-sampling committee of the Chamber of Mines, of the Mines Department, and of the Mine Officials to enable them to test more recently introduced technique, not only in a laboratory, but, what is of more importance to them, also under actual working conditions of the mines; these recent methods include Palmer's method, Read's method, Greenburg and Smith's method, Owen's method, and the electrical precipitation method. Dust, of course, collects in the air of mines, owing to absence of efficient through ventilation; local ventilation is of no value. Dr. Mavrogordato suggests that Dr. Leonard Hill's kata-thermometer, because it is able to detect ventilation currents and estimate velocity of air movement, may give more information as to underground health conditions than any other single procedure; but we will require to know the minimum linear velocity which will keep dust diluted and which will dissipate any dust produced owing to some failure in the usual precautions.

It may surely be regarded as very creditable to have reduced the number of cases of silicosis from 25 per cent. in 1911 to less than 3.5 in 1923, an improvement which is attributed to the use of water to prevent dust production and also to some attempt to remove dust by mechanical ventilation. To reduce the case-incidence further, some fresh factor or factors must be introduced. Dr. Mavrogordato suggests (1) systematic through ventilation to the working places; (2) a preliminary treatment of the water used for spraying and washing down; and (3) perhaps the use of exhaust-hoods (Sheffield hood principle) in certain circumstances. There is evidence that "tube-trouble"—the machine water-tubes—may be responsible for intermittent exposure to relatively dense clouds of dust; it is considered that such intermittent exposure is the deciding factor in producing the disease in susceptible human subjects. The returns show that about 70 per cent. of the silicotic cases occur in men who have used machine drills at some time or other, although such men only amount to about 30 per cent. of the men employed underground at any one time. It seems reasonable then to suspect the machine-drills, and further research is planned to elucidate such problems.

THE INFLUENCE OF THE OVARY ON PITUITARY SECRETION.

RECENT researches on the condition known as pseudo-pregnancy have a direct bearing on the problem as to the cause of parturition. In the dog, rabbit, and some other animals the corpus luteum persists during pseudo-pregnancy in the same kind of way as it does during true pregnancy, and the uterus and mammary glands undergo growth in correlation with the growth of the corpus luteum. In the rabbit, which normally only ovulates after coition, the condition of pseudo-pregnancy can be induced by permitting the doe to have a sterile coition (as with a vasectomised buck). The corpus luteum after being apparently functionally active eventually undergoes involution, and in association with this process the uterus also regresses and the mammary glands begin to secrete milk. There is no clear evidence that the ovary has any direct influence in bringing about parturition.

In the current number of the *Journal of Physiology* W. E. Dixon and F. H. A. Marshall describe four experiments in which extracts of whole ovaries of rabbit and sow were employed, and the precise stage of pregnancy or of the oestrous cycle noted at which the animals were killed. Boiled Ringer extract of ovaries—rabbit and sow—was injected into the vein in dogs, the cerebro-spinal fluid collected at suitable intervals, and its effect on the uterus of a virgin guinea-pig tested in the usual way. Dixon

¹ Publications of the South African Institute for Medical Research, edited by W. Watkins-Pitchford, M.D. No. XVII., The Value of the Konimeter—being an Investigation into the Methods and Results of Dust Sampling as at Present Practised in the Mines of the Witwatersrand. By A. Mavrogordato, M.A., M.R.C.S., L.R.C.P., with the collaboration of J. Boyd, J. Innes, E. MacEwen, A. Pulford, L. G. Ray, G. D. Maynard, J. Moir, E. Cluver. Johannesburg. 5s.

had found that certain ovarian commercial extracts had an exciting effect on the pituitary gland when injected into a vein. If the cerebro-spinal fluid collected from this animal caused contraction of the virgin uterus suspended in Ringer's fluid, this showed that pituitrin had been secreted into the C.S.F. Normal ovarian secretion does not act directly in promoting uterine contraction, but does so indirectly through its action on the pituitary body. Moreover, this action is inhibited during pregnancy by the corpus luteum. The injection experiments show that in the presence of the fully formed and presumably functional corpora lutea, the normal ovarian secretion is largely in abeyance, and this is the condition for a short part of the time between the heat periods, but more particularly during pregnancy. The corpus luteum would seem so to dominate the ovarian metabolism at these periods that the ovarian secretion, which at other times activates the pituitary, is inhibited or else is neutralised by the secretion coming from the corpus luteum. At the close of pregnancy, when the corpora lutea are in an advanced state of involution, the normal ovarian secretory activity is once more produced, and the pituitary is excited to secrete in greater quantity. When the threshold stimulus of the pituitary secretion upon the uterus is reached and passed, the pains of labour set in and parturition results. The growing irritability of the uterus in the later stages of pregnancy is explained as being functionally correlated with the involution of the corpus luteum. The authors do not suggest that the ovario-pituitary endocrine mechanism is the sole factor in producing the labour-pains, as no doubt the foetus itself acts as a direct stimulus. The onset of labour cannot easily be accounted for without postulating some further exciting cause apart from the foetus and uterus. The authors agree that the phenomena attending the termination of pseudo-pregnancy point to the conclusion that the occurrence of a certain stage in the cyclic activity of the ovary is a factor in parturition.

Ovarian secretion accordingly does not bring about parturition by acting directly on the muscles of the uterus, although the secretion of the pituitary has a definite specific action on the muscles of the uterus; and the secretion of the ovary in the absence of fully formed (and therefore presumably functional) corpora lutea has a definite specific stimulating effect in promoting pituitary secretion. The secretion of the ovary in the presence of such corpora lutea, on the other hand, has no such effect, its action on the pituitary gland being completely negative. The corpus luteum so dominates the ovarian metabolism during pregnancy as to inhibit the normal ovarian secretion; but with the involution of the corpus luteum at the close of pregnancy the uterus shows an increased irritability, and eventually, when the ovarian endocrine mechanism is sufficiently re-established, the secretion, working through the intermediation of the pituitary, becomes an important factor in bringing about labour. The action of the ovary upon the pituitary undergoes a similar variation in the absence of pregnancy and during the oestrous cycle, the determining factor being whether corpora lutea are present or absent.

GERMAN LEARNING.

GERMAN medical science has sustained a heavy loss by the recent death of three eminent medical men, Prof. Strümpell, of Leipzig, Prof. Bumm and Prof. Morgenroth, of Berlin. Prof. Strümpell was born in 1852 in Dorpat in the Baltic Provinces of the Russian Empire, where his father held the chair of philosophy at the former German university. Strümpell began his career at the University of Leipzig, where he became assistant to Wunderlich, the physiologist, and to Wagner, the pathologist. He was later appointed ordinary professor of medicine at the universities of Erlangen, Breslau, and finally at Leipzig, where

he remained until his death. Strümpell's work is well known; his great handbook of special pathology and therapy has been published in 25 editions, apart from many translations. His first work was on the study of renal diseases, but afterwards he devoted himself nearly exclusively to the diseases of the nerves. His researches on tabes dorsalis, muscular atrophy, infantile paralysis, neuritis, and traumatic neurosis were published in *Deutsche Zeitschrift für Nervenheilkunde*, of which he was the editor. Strümpell was a man of great culture; his style, both in speaking and writing, was clear and precise, and he was an accomplished musician. A few months before his death he finished his memoirs which have recently been published. Prof. Bumm was born in 1857 in Würzburg, Bavaria. He became assistant to Scanzoni at the university of his native town, the greatest German gynaecologist and obstetrician of the time. Having occupied the chair of gynaecology successively at the Universities of Bâle and Halle, Bumm was called to Berlin in 1904. His chief study was gonorrhoea in women, puerperal fever, and the treatment of cancer by radium. Apart from the pathological and technical side of women's diseases, he was much interested in the problems of population. His renown as a gynaecologist and obstetrician was very great, and he had, perhaps, the largest consultant practice in Germany. Latterly he suffered from gall-stones which, whilst he was on a holiday in Munich, produced a perforation of the gall-bladder, necessitating an immediate operation which unfortunately proved fatal. Prof. Morgenroth was less known to the general public than Bumm, as he was not engaged in private practice. He was born in Bamberg, Bavaria, and after his university training became an assistant to Ehrlich at Frankfurt, where he published his first researches concerning immunisation and hæmolysins. Having worked for some time at the German zoological station at Naples, he was appointed, after his return home, as assistant to the pathological institute of Berlin and afterwards became head of the chemotherapeutic department of the Robert Koch Institute. In this capacity he made his most important researches; he discovered optochin, a specific agent against infection by pneumococci, eucupin and vuzin, agents against the infection of wounds, which were successfully used during the war, and lately rivanol, a valuable agent against infection by staphylococci. He died at the age of 53 years from leukæmia.

THE INFLUENCE OF THE DRAMA.

PROPENSITIES which are labelled virtues or vices often are not so per se, and in a similar way it is easy to name a thing as a luxury and treat it as such when, if it were properly accepted in the scheme of life, it would be revealed as a necessity. This truism was neatly put by Sir StClair Thomson, the President at the social evening at the Royal Society of Medicine on Jan. 19th, in introducing Miss Lena Ashwell (Lady Simson) to the Fellows and their guests. He showed that it was possible to regard the arts as holding the same position towards the mental well-being of society as vitamins were considered to hold in relation to bodily health. Upon this introduction Miss Ashwell gave a witty and suggestive address on the Drama as a Necessity of Civilised Life. She described the organising of entertainment parties to operate in France, Egypt, Palestine, and other areas during the war, and proved, to an audience that wanted no convincing, the value of these parties to the morale of the forces. In this way and in many others the genuine interest which the mass of the population of this country take in the drama was, said Miss Ashwell, abundantly displayed, but, unfortunately, this old and necessary art was now giving place to an unworthy competitor, the cinema. This country, she continued, possessed the richest dramatic literature of any nation since the time of

the ancient Greeks, but it was only rarely that good plays, old-time or modern, could be seen even in the large provincial centres. The reason was partly that the taxation of the theatre as a luxury caused the production of good plays to be generally attended by a financial loss to those producing them, but this was only part of the story, the apathy of the populace being another contributing factor. It would be a national calamity if the drama were allowed to die out and the presentation of films, mainly preposterous and of transatlantic origin, should take its place, for the cinema influence was often deplorable, the aspects of life portrayed being unreal and vicious. Miss Ashwell's address was a vigorous plea for the recognition of the drama as a necessity in social life, alike as an educational medium and a source of refreshment.

DR. LOMAX AND HIS CRITICS.

IN November last we reviewed a pamphlet having this heading, which was written by Dr. Montagu Lomax as a reply to the personal references to himself contained in the report of the Committee on the Administration of Mental Hospitals, 1922. Dr. Lomax calls our attention to the fact that certain of his words—namely, "Governments do not go to the trouble and expense of appointing Departmental Committees to inquire into vague and unsubstantial charges"—were meant to imply that his charges were not of this nature, whereas in our article it is suggested that his charges were by his own confession vague and unsubstantial. This has caused him annoyance, but, while regretting that fact, we feel that Dr. Lomax, considering the charges which he has brought against others, should be slow to resent a small joke at his unlucky phraseology, and one which was so obvious that it cannot possibly have affected his position as a would-be reformer.

AN announcement has appeared in the daily press to the effect that Sir Harold Stiles is resigning the Chair of Regius Professor of Clinical Surgery in the University of Edinburgh, and a little explanation is required. Prof. Stiles's term of office does not expire until March 21st, his successor being appointed at the opening of the summer session, one month later. Prof. Stiles gave notice of his intention to vacate his chair to the authorities in order to give them ample time in which to appoint a successor, but the significance of Sir Harold Stiles's action lies in his resolve to withdraw from private practice simultaneously with his resignation of his University and hospital appointments. His professional colleagues will recognise that this is the action of a single-minded man, who has resolved that he will not create leisure in which to discharge private work by the easy process of giving up honorary or official duties.

THE LATE DR. J. D. WILLIAMS.—John David Williams, M.B., C.M. Edin., died on Jan. 23rd at Plasgwyn, Pentrefelin, Portmadoc, in his sixty-ninth year. He was the son of a farmer, and was born at Thewydd, Llanfrothen, Merionethshire. He started life as a quarryman, but when 18 years of age he determined to become a schoolmaster, and having gained a scholarship qualified as a certificated teacher at Bangor Normal College. He subsequently became headmaster of schools at Llanidloes, Llfrothen, and Tanygrisiau. Then he resolved to become a medical practitioner, and proceeded to the University of Edinburgh, where after four years' study he graduated M.B., C.M. in 1891, and in 1892 obtained the degree of Bachelor of Science in Public Health. He was for a time assistant physician to the Chester and District Skin Dispensary; he then took up general practice in Shrewsbury, retiring two years ago to Pentrefelin. In Shrewsbury he held several public appointments, being medical referee for some important local institutions, and honorary surgeon and lecturer to the St. John Ambulance Brigade. He was a Fellow of the Royal Institute of Public Health and a president of the Shropshire and Mid-Wales Branch of the British Medical Association.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CVII.—THE TREATMENT OF GINGIVITIS.

THE word gingivitis implies inflammation of the gingivæ or soft tissues in the immediate vicinity of the teeth, and should not in any way be confused with chronic general periodontitis, more colloquially known as pyorrhœa alveolaris, the latter being a disease of the periodontal membrane, the delicate structure which closely surrounds the tooth root, and is therefore a deeper seated disease. Cases of chronic general periodontitis may be met with where there is no inflammation of the gingivæ; this may be explained by the fact that the inflammation of the periodontal membrane is situated at the apex of the root. More often, however, it is the gingivitis which draws attention to the other condition. Gingivitis may be divided up into (1) marginal, (2) general, (3) chronic, and (4) ulcerative.

Marginal Gingivitis.

Marginal gingivitis is usually catarrhal in character and may be found both in children and adults. The free margins of the gums appear red, congested, and swollen. The patient may or may not complain of soreness, the gums tend to bleed when touched, and if squeezed a thick muco-purulent discharge often exudes from around the necks of the teeth.

The normal gingival trough is accentuated forming a pocket; this pocket is caused by the swelling of mucous membrane and not through loss of tissue as in the case of periodontal disease. This may be demonstrated by gently investigating the pocket with a probe, when the pocket will be found to end at the neck of the tooth. A careful examination will show that the free margin of the gums have advanced towards the biting edge of the tooth covering part of the crown. The condition may become purulent, and not infrequently the interdental papillæ become hypertrophied and the whole gum swollen, the chronic hypertrophic gingivitis more often found in children.

One of the chief causes of gingivitis is mouth-breathing. Constant friction of the cheeks against the teeth, efficient mastication of food, and above all a constant flow of saliva washing away debris are necessary to bring about the physiological conditions. Mastication will aid in inducing a normal blood-supply to the teeth, but the presence of functionless or tender teeth in the mouth not only provides infected foci, but impedes normal functions. Mouth-breathing allows any particles of food remaining around the front teeth to dry and putrefy, and there is no cleansing action by saliva. Apart from the need to wash away bacteria the gingival organ secretes actually substances which, if allowed to dry, form calcareous rough deposits injurious to soft tissues. In a mouth-breather the gingivitis is generally limited to the anterior teeth.

Other mechanical causes may be traced to overhanging edges of fillings, but these tend to cause a chronic hypertrophic condition locally. Continued and indiscriminate use of floss silk may cause damage to mucous membrane if forced between the teeth in such a way as to cut the gums, but perhaps the most dangerous is the tooth-pick. This is seldom kept even socially clean, and is often stabbed into the gum in a vain endeavour to remove food lodged between two teeth, and then replaced in the waistcoat pocket.

General Gingivitis.

General gingivitis is commonly found as a sequela of fevers, also in wasting diseases. This may be largely attributed to loss of tone of muscles of mastication following on a liquid diet. The sticky, starchy, and sugary foods, popular in convalescence, unless thoroughly acted upon by ptyaline, form somewhat insoluble substances which stick to the teeth and

putrefy. The ætiology of the gingivitis of pregnancy appears to be somewhat obscure.

Metallic poisons, particularly lead and mercury, lead to general gingivitis which, if not treated, may become serious. Care must be taken to differentiate between a true lead poisoning and other conditions such as tartar or black pigmentation seen in dark-skinned races. A true lead poisoning will usually be characterised by general conditions such as colic or wrist-drop, and the blue line situated on the gum around the lower incisors. Patients undergoing a course of mercury treatment frequently develop a severe gingivitis, and the teeth should be put into a healthy condition before such a course is begun, since in an unhealthy mouth mercury is deposited in minute globules at the gingivæ where they become turned into the sulphide, which acts as a powerful cell poison.

Chronic Gingivitis.

Chronic gingivitis is nearly always due to some mechanical irritation, such as the wearing of a denture at night, and lack of hygiene. In some cases diet may be a factor, such as hot sauces; one case that came under observation appeared to be caused by a sour-milk diet.

The Routine to be Followed by Patients.

In all cases of marginal, general, or chronic gingivitis the cause should be looked for and removed. Where there is mouth-breathing, then any post-nasal growth should receive attention, but in order to break the habit of mouth-breathing, which may persist although there is no nasal obstruction, the patient should wear an oral screen at night. This screen consists of a piece of vulcanite or metal made to fit against the labial aspect of the gums as far back on either side as possible. Thus the screen will be held in position by the pressure of the lips in front, and owing to the shape of the sulci there will be little possibility of much movement or any tendency to swallow it, apart from the fact that the screen is of some size. After a week the patient becomes used to the appliance and will sleep comfortably. In all cases the gums will require an astringent mouth-wash, and the following will be found useful:—

R	Zinci chloridi	aa gr. ii.
	Zinci sulphatis	aa gr. ii.
	Spiritus chloroformi	℥v.
	Aqua menth. pip.	ad 3ss.

Misce.

Ten drops in half a tumbler of water as a mouth-wash. All tartar should be removed before using such a mouth-wash.

Where there are tags of gum between the teeth an application of pure trichloro-acetic acid may be found useful, administered for not longer than 30 seconds, to be repeated if necessary in a week's time. It is best applied to the tag of gum on a small pledget of wool. An excellent routine for the patient to carry out daily would be somewhat as follows. In the morning two or three drops of some cleansing preparation, as milton, should be placed on the tooth-brush and all the teeth should be carefully cleaned and the mouth then rinsed with the zinc astringent mouth-wash. Next, the gums should be massaged by pinching the gums with the finger and thumb towards the crowns of the teeth, and finally rubbing laterally with the index-finger. During the day the mouth should be rinsed out with the zinc mouth-wash two or three times. At bed-time some non-gritty tooth-paste may be used in preference to the milton, and this should be followed by careful massage with the fingers, using glycerine and tannic acid B.P. preparation. Some people, however, do not tolerate tannic acid for more than a week, in which case some bland preparation as myrrh and borax is substituted, followed by a rinse of water as cold as the patient can stand. It is of importance for the patient to have a small tooth-brush and one which is fairly stiff; if the bristles show a tendency to come out it should be discarded. After use the brush should be rinsed and placed in a suitable

position to dry. In the case of hypertrophic gingivitis the application of ferro-pyrin on wool to the pockets once a day will be helpful, this drug being a powerful astringent and anodyne. The treatment of gingivitis by electrical means is a specialised subject and should be carried out only by experts. Gingivitis caused by wearing a denture at night will clear up when the habit is discontinued and with constant mouth-wash. Poisoning from mercury and lead is not difficult to deal with once the poison is discontinued. Hydrogen peroxide may be used with great success in the case of mercury, but if the gums have started to ulcerate then the condition may be dealt with as though it was ulcerative gingivitis.

Ulcerative Gingivitis.

A condition prevalent during the late war was known as "trench-mouth." Of this condition two varieties are described: a diphtheroid type, which is superficial and somewhat less severe than the second type, which is ulcero-membranous and may involve the whole of the buccal mucous membrane and penetrate to the bone. In both types the *Bacillus fusiformis* of Vincent's angina is found besides the pyogenic bacteria always associated with such ulcerative conditions. The appearance of both forms is typical. Ulceration usually commences around a septic tooth or badly fitting crown. Within 48 hours the infection spreads to both jaws and the gums become swollen with grey slough around the teeth. If the infection is of great virulence the teeth become loose. The breath is very foul and the temperature may rise to 102° F. The infection may spread to the tonsils and pharynx. Unless dealt with, the teeth may be lost, and serious scarring take place from the cheeks becoming attached to the gums.

In treating such a condition it is most unwise to extract teeth; this procedure will only allow the condition to penetrate deeper. No great harm will be done by leaving in infected teeth until the condition is improved, unless, of course, an abscess is present. The patient should have a purge followed by saline each morning for four days, and his general health maintained by tonics containing iron and arsenic. Locally, the mouth should be cleaned up by constant rinsing with a chlorine preparation such as eusol, milton, or fecto, about a teaspoonful to a glassful of water. The ulcerated part should be swabbed over with the following preparation:—

R	Liq. arsenicalis	aa 3iii.
	Vin. ipecacuanhæ	aa 3iii.
	Glycerine	3ii.

Misce.

The patient may suck not more than six 5-gr. tablets of potassium chlorate a day. In a week the patient should be nearly recovered, and the treatment for simple gingivitis may be carried out, but the gums should not be massaged until the mucous membrane has fully recovered. All vessels, especially drinking glasses, should be carefully boiled as the disease is easily communicable.

The best method of applying drugs to the buccal mucous membrane is by the use of wooden applicators bound with cotton-wool such as are employed in aural surgery; these should be burnt after use.

Dental Surgeon to University College Hospital
Dental Dept.; Assistant Dental Surgeon,
West London Hospital.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC.—A post-graduate course will be held at the hospital, Queen-square, Bloomsbury, W.C., from Feb. 2nd to March 27th. The course will consist of the following subjects: Out-patient Clinics, Clinical Lectures and Demonstrations, Lectures on the Anatomy and Physiology of the Nervous System (if sufficient applicants), Lectures on the Pathology of the Nervous System, Clinical Demonstrations on Methods of Examination (if sufficient applicants), and Lectures and Demonstrations on the Neurology of the Eye. Copies of the syllabus may be obtained on application to the Dean of the Medical School.

PROCEEDINGS OF THE ROYAL COMMISSION ON NATIONAL HEALTH INSURANCE.

INTRODUCTORY NOTE.

THE Royal Commission on National Health Insurance, under the chairmanship of Lord Lawrence of Kingsgate, has held 14 sittings and is now sitting weekly. The evidence given at the first six meetings by the official witnesses of the Ministry of Health and the Scottish Board of Health supplements and elaborates the printed volume of statements put in by the Government departments in question. This official evidence, taken in conjunction with the statements referred to, embraces a review of the whole of the working of the National Health Insurance system.

We propose to give a résumé of those parts of the official evidence which we consider to be of interest to our readers. Taken as a whole, this evidence gives in a concise and comprehensive form an account of the scheme in which medical men play so important a part, and of which—especially in its more general, as distinct from its medical features—they are, we believe, not too well informed.

This summary of the earlier evidence, followed by a short account of the evidence at more recent meetings given by approved societies, will prepare our readers' minds for the evidence to be given in April on behalf of the insurance practitioners (on the lines of the statement given in our issue of Jan. 10th, p. 95) which we hope to summarise from week to week as the official reports are issued. It is important to note the scope of the official evidence given at this stage. At the outset the Chairman indicated that it was not proposed to invite, for the time being, from the Ministry's representatives, any criticisms of the scheme or proposals for its amendment. It was desired to get a clear view of the system as it is and later to hear the officers of the department on points of criticism and suggestions for amendment.

References to the official statement which has been issued as an appendix in four sections are given thus: Section A, para. 69, is shown as "App. A. 69," and references to the oral evidence thus—Q. 1369.

THE SCOPE OF THE INSURANCE SCHEME.

Who are Insurable?

(App. A. 22-3.) The great majority of employed persons between the ages of 16 and 70 are compulsorily insured, the usual test being whether there is a contract of service. Seamen are included under a special provision, and certain classes of persons are also specially included, who may not be technically under a contract of service, but who are, broadly speaking, in the position of employees working for a master.

Exempted Employments.

(App. A. 4 and 5.) Clerical and other non-manual workers employed at a rate of remuneration exceeding £250 a year are excluded and also many specified employments which are either not the worker's principal means of livelihood, or are employments in which the worker is protected by the terms of his engagement against risks which the insurance scheme is intended to meet. As regards the latter class, no provision need be made by the employer corresponding to medical benefit or any other benefits except sickness and disablement benefit, but the scales of sick pay and pension are frequently so far in excess of the statutory sickness and disablement benefits that the employees are probably not at any serious disadvantage in this respect. Broadly speaking the effect of this provision is to exclude

from the insurance scheme all established civil servants and certain analogous grades of Crown employees, the police throughout the country, the majority of Poor-law and asylum officers, the permanent clerical staffs (and in some cases workmen) of many local authorities, and clerks and permanent officials of railway companies.

The Wages Limit.

(App. A. 12.) The wages or salary limit which, it will be noted, is not a limit of total income and does not apply at all to manual workers—was raised from £160 to £250 in 1919. This amendment was merely designed to adjust the remuneration limit to changed economic conditions, and although no precise statistics are available it is probable that the number of insurable persons was not greatly enlarged thereby. The following questions to Sir Walter Kinnear, the Controller of Insurance, as affecting this class, are of interest:—

(Q. 107.) I notice in such bodies as Stock Exchange clerks, insurance officials, warehousemen, travellers, and people of that class, there seems to be an enormous exit from insurance when people get round about 23 to 25 years of age. Do you think that is to be attributed to people going over the income limit?—I can assign no other cause, unless it may happen that their terms are so altered that they pass away from a contract of service.

And again:—

(Q. 110, 111.) Is it not rather difficult to defend an arrangement under which so large a number of young people are compulsorily brought into insurance and compulsorily ejected from it after a few years?—They have the right to remain in insurance as voluntary contributors at the same premium.—Do they ever avail themselves of that right?—Very few do.

Asked whether at the moment he knew of any convenient way of determining whether a person should be insured otherwise than by the present automatic system, the Controller said that he did not.

Doubtful Questions of Insurability.

(App. A. 16.) The Minister is charged with the judicial function of determining, subject to an appeal to the High Court on a question of law, whether a class of employment or the employment of a particular person is within the scope of compulsory insurance and, if so, who is the employer.

As to difficulties in connexion with the manual labour test, the witness said:—

(Q. 35.) We had quite considerable difficulty in the early days, but as a result of experience and legal decisions certain broad determining principles have been laid down and we find our decisions, as a rule, are accepted without question and we have very little difficulty now in this connexion.

(Q. 148, 149.) As a reason for the exclusion of the non-manual worker at £250 when the benefits of the Act are conferred on the manual worker with wages up to any figure, the witness suggested that the former was more accustomed to making provision for himself and had, on the average, greater security of tenure in his employment.

Exempt Persons.

(App. A. 21.) Exempt persons are to be distinguished from excepted persons, who are outside the Act altogether. The exempt person is one who is engaged in employment within the meaning of the Acts, but has voluntarily obtained a certificate exempting him from paying any contribution on the ground that he has a private income or is ordinarily dependent on some other person. The employer in this case remains liable to pay his own share of the contributions, since if he were free from contributing for exempt persons there might be a tendency to give employment to them in preference to other workers. The number of exempt persons is very small, amounting in England to 33,600, or about $\frac{1}{4}$ per cent. of the population. The employers' contributions are used to provide them with medical benefit, and it appears that 90 per cent. of exempt persons take the trouble to go through considerable formalities in order to get medical benefit.

(Q. 166.) The exempt person is the only person who gets something for nothing?—As far as his proportion of the contribution is concerned, that is so.

Voluntary Contributors.

(Q. 42.) It was thought at the inception of the Act of 1911 that there would be a large number of voluntary contributors, but these expectations were not realised. The scheme for the admission of such persons to insurance was considerably restricted in 1918, and there are now in England only about 30,000 voluntary contributors. They are mainly composed of persons who have been insured as employed contributors for not less than two years and have elected to remain on as voluntary contributors.

Number of Insured Persons.

(App. A. 27.) The number of insured persons in England and Wales was 11½ millions in 1912 and 13½ millions in 1922. (Including Scotland, the total is about 15 millions. Notes on the Scottish evidence will be given later.) Compared with the Census figures of 1911—the last which are available for this purpose—the following particulars are of interest:—

The number of occupied persons in England and Wales at that date between the ages of 16 and 75 (? 70) was 15,200,000. Of these 1½ million are employers or persons working on their account; 270,000 are made up of officers in the Army and Navy, ministers of religion, professional men, &c. This leaves a total of nearly 13½ millions who may be said to be employed in the broad sense of the term, of whom, as stated above, 11½ millions were insured in 1912. The balance of two millions is accounted for by persons whose work does not come within the definition of contract of service or apprenticeship and by non-manual workers over the salary limit and other persons engaged in excepted employments.

Collection of Contributions.

(App. A. 28, 29.) The Health Insurance scheme is contributory in character. The funds are contributed by insured persons, their employers, and the State; the contributions of insured persons and their employers consist in the main of weekly payments, and those of the State take the form of a grant of two-ninths of the sums expended on benefits and their administration. The weekly contribution in general in the case of employed contributors is 10d. (9d. for females), of which 5d. is normally payable by the employer and the remainder by the worker. (App. A. 31-8.) The employer is responsible for paying the joint contribution and may recover the worker's share by deducting it from his wages. During unemployment or sickness no contributions need be paid. They may be paid by the worker during unemployment to avoid a reduction in the cash benefits. No arrears accrue during notified sickness.

The Stamping of Contribution Cards.

(App. A. 38.) Contributions are usually paid by means of stamps affixed by the employer to cards which the worker gives up half-yearly to his society. It is the duty of the worker to obtain a half-yearly card from his approved society or from a post office, and to produce it to his employer on commencing employment and at other times when required by the employer. But, as the onus of paying contributions is on the employer, emergency cards providing for a single weekly stamp are available at post offices for use by employers whose employees fail to produce cards, and it is the duty of the employer to obtain and stamp these cards where the ordinary cards are not forthcoming.

Enforcement of Payment of Contributions.— Inspection and Prosecution.

(App. A. 40.) The payment of contributions is enforced by the Ministry by means of inspection, correspondence, and, where necessary, prosecution. An inspector appointed by the Minister has power

to enter at all reasonable times any place (except a private dwelling-house which is not a workshop), to require the production of cards, &c., and to satisfy himself generally that the Acts are being complied with. Routine visits are made to factories, shops, farms, &c., but private employers are in general visited only on receipt of a complaint, although the inspector has no right of entry in such a case and must withdraw if requested to do so. Proceedings generally must be brought within one year after the offence. During the year 1923 the number of prosecutions in England was 984.

(Q. 24.) Asked whether there was any evidence of hostility to the scheme on the part of employers or employees, the Controller said that there was a good deal of hostility in the early days, partly owing, he thought, to political considerations, but that it had died down. Of course, he said, we get complaints from time to time from individuals. That is inseparable from the working of a scheme which affects 15,000,000 bread-winners and practically every employer throughout the country. But, he said, there is no evidence of general hostility to the Act now. As to evasion of the payment of contributions, Sir Walter Kinnear said:—

(Q. 213.) Our calculations lead us to think that on the whole we collect about 99 per cent. of the contributions which are due. We recognise that there is a certain degree of non-compliance amongst casually employed persons, and to a more limited extent amongst domestic servants.

Special Classes of Workers.

Interesting provisions will be found in the evidence as to problems affecting special classes of workers, of which one or two short notes here will give a sufficient indication. (App. A. 55.) In the case of out-workers, for instance, who work at home for several employers, a special system of "units" of earnings (equivalent to a full week's earnings if working for one employer) has had to be devised, under which each employer stamps a card for each unit instead of for each week without regard to the question whether another contribution has already been paid in the same week by another employer.

(App. A. 48-54.) Again, special provisions for the contributions and benefits of seamen in the mercantile marine are necessary. There is a reduced contribution in the case of foreign-going ships, in view of the fact that the employers are liable under the Merchant Shipping Acts to provide the seaman with medical treatment and maintenance during sickness until they return him to a home port. As regards foreign domiciled seamen, employers' contributions are paid quarterly to the Ministry, and the amount collected, which is approximately £23,000 a year, at the present time, is credited to a special fund, commonly known as the Lascar Fund, and is used for the provision of pensions for insured seamen under a scheme administered by a governing body comprising representatives of shipowners and insured persons.

The Controller's evidence on the subject of cash benefits and medical certification will be summarised later, after some of the main official evidence with regard to medical benefit has been given.

THE fourteenth meeting of the Commission was held at the Home Office, Whitehall, on Jan. 22nd, Lord Lawrence of Kingsgate in the chair. Evidence was received from three miners' societies—viz., the Scottish Miners' Federation Approved Society (Mr. James Gold), the Lancashire and Cheshire Miners' Permanent Approved Society (Mr. D. Shaw), and the Lancashire and Cheshire Miners' Federation Approved Society (Mr. Lee Shaw). The special difficulties arising in societies composed wholly or largely of miners were represented by these witnesses—in particular the inability to give additional benefits owing to the unavoidable heavy expenditure on normal benefits for those engaged in the mining industry. Proof copies of oral evidence given at the meeting, Jan. 8th, are now on sale at H.M. Stationery Office (1s. 6d.).

SOME REFLECTIONS ON SECOND-HAND CARS: WITH HINTS ON THEIR PURCHASE.

BY J. MARSHALL, M.I.A.E.,

LONDON MANAGER OF MESSRS. MANN, EGERTON AND CO., LTD.;
OFFICIAL CONSULTING ENGINEERS, MEDICAL INSURANCE
AGENCY.

THE second-hand car problem, both from the owner's and the motor-car dealer's point of view, is too often a source of tribulation and of hard thoughts. The owner naturally seeks to obtain the fullest market value he can for his property and the dealer to ascertain the lowest price at which he can get the car. This question is probably one of the most difficult the dealer has to face. The average owner is disposed to consider the value of his used car at far in excess of its actual worth on the market, and where the medical man appears especially inclined to go wrong is in respect to purchases made in the two years following the war period. During this time enormous prices, and in many cases large premiums, were obtained, with the result that values became quite fictitious. When the unfortunate owner of a car bought during 1919 and 1920 proposes to sell it he is horrified at being offered a mere fraction of the purchase money, forgetting to what extent values have decreased during the intervening years.

The particular value of each second-hand car is, apart from its condition, based on the present-day prices of a new car of similar make. The owner when considering the exchange of his used car for a new one is often inclined, without much consideration, to accept the highest offer made for the used car. This is not necessarily a wise decision. The owner should ask himself the following questions: (1) Am I getting good value in the price being paid for the new car? (2) Am I buying a car which is not a good seller? (3) Has the car being offered to me a good second-hand value?

If the car is not good value for the money asked, it can be assumed that the owner will be offered a high price for his used car. If it is not a good seller, any small increase in the value allowed for the second-hand car will not anything like cover the heavy depreciation which will occur immediately the car is put on the road. It may be that a car sells freely but has a low second-hand value. Thus it happens that many fairly high-priced cars will be found to be cheapest in the long run, largely owing to their low depreciation—i.e., high second-hand value. My experience is that too little attention is paid to these points by would-be purchasers, many being inclined to consider only the low initial cost.

The Purchase of a Used Car.

The purchase of a used car bristles with difficulties. Here especially does it pay a purchaser to deal with a firm which is careful of its reputation in the sale of used vehicles. Such a firm gives no guarantee with a used car, but studies the interests of clients by careful examinations and submits a candid opinion as to the car's mechanical condition and worth. From a reliable firm a first-rate used car should be obtainable if the owner is prepared to pay a fairly good price. It is rarely possible, although it does happen, at long intervals, that a first-class car can be bought at a "give away" figure.

The "Points" of a Used Car.

The Trial Run.—When the purchaser has clearly in his mind the type of body required, and has decided that the h.p., age, and finally the price, which is practically governed by the last two points, are, broadly speaking, satisfactory, a run on the road should be taken. The trial should, if possible, include a steep and a long hill so that some idea as to the power, road performance, and general silence of the car may be obtained. These being satisfactory, the following vital points should be carefully examined.

(a) *Engine.*—Without going into technical details, some idea of the condition of the engine can be arrived at by listening when it is running idle, and also under load. If any knocking is heard the opinion of an expert should be obtained, for it may prove vastly expensive to get rid of knocking. It may, and often does, involve the renewal or extensive repair of loose gudgeon-pins, slack pistons, broken rings, broken big-end connecting-rod bushes, and sloppy main bearings. Knocks are very elusive and difficult to locate definitely, although, broadly speaking, where there is a distinct thump it may be taken that the bearings on either end of the connecting rod are badly worn. Where this occurs the engine has to be taken out and this procedure may cost, over and above the cost of any broken parts replaced, anything up to £15.

(b) *Steering Connexions.*—Front wheels should be examined for play in bearings and swivel-pins. The amount of play can be decided by jacking up the wheel and jerking the wheel itself sharply in and out and sideways. There should be practically no movement either way.

(c) *The Gear-box* should be examined for worn bearings and worn teeth on gear wheels. This is quite simply done, as the ordinary gear-box cover is removable with the undoing of two or three wing nuts. To test for wear in the bushes, jerk the shafts sharply up and down, when there should be no movement. Excessive wear of the gear-wheel teeth is shown by a flat on the teeth about one-third of the way down. When this is found it does not follow that the gears are not sound; generally the effect of worn teeth is a noisy gear-box, especially in the lower gears.

(d) *Universal Joints.*—Usually these are made of fabric and the holes in the joints may be found to have practically worn through or the material itself to be badly twisted, causing the propeller shaft to run out of truth, with consequent noisy transmission. The effect of a propeller running out of truth is to upset the balance of the whole car, causing the gear-box and back axle to be noisy, in addition to which there is intense vibration throughout. The cost of replacement of the worn fabric joints would be roughly 30s. each or, if of the metal type, approximately £6. The metal type is not often found on up-to-date cars, since the fabric type is much easier to replace and requires no attention under running conditions.

(e) *Back Axle.*—If both wheels are jacked off the ground the end-play of the differential can be tested by pressing each wheel in turn in and out and noting the movement; end-play should be slight. If, when the car was tried on the road, the back axle was found to be noisy it would require careful examination, particularly as to end-play in the bevel pinion.

The Lighting and Starting System is a vital part of the car and is probably the most expensive part. Great care and attention should be given to the inspection of the various units. The battery should not be forgotten; its condition can easily be determined even by a superficial glance at the plates and terminals. A glance at the plates will show whether they are sulphated or not, that is, whether covered with a grey-green deposit. When the plates are in this condition, which is obvious even to the tyro, it is a sign either that the battery is worn out or that it requires new plates, an expensive process which would probably cost about £4-£5. Whilst on a trial run, the opportunity should be taken to see whether the dynamo is charging at slow engine speeds, such as 15 miles an hour on top gear, since the doctor's rounds often involve a good deal of low-speed driving. When the engine is speeded up to a road speed of 25 miles per hour on top gear with all lights on, the current taken out should be only slightly more than that going in, this consumption being shown on the meter on the dashboard. In view of the fact that the lighting and starting system

of a doctor's car is used extensively it is essential that the battery be of large capacity. Much depends on the size of the engine, but for an ordinary car of, say, 12 h.p., the battery should be of a capacity of about 80 ampère hours; otherwise it will constantly be found necessary to have it charged on the board.

Body Work.—It is not difficult to estimate the condition of the body as to paint-work and upholstery, but not so easy for the average purchaser to say whether it is a good, bad, or indifferent one. New bodies vary in price as much as 100 per cent., type for type—that is to say, some first-class coach-builders can obtain double the price for their products that a second-class firm could safely demand. A good body will always have its value. It looks well, paint-work is good, and rattles and squeaks are absent. These factors have a great influence on the worth of a second-hand vehicle, particularly where closed bodies are involved.

Conclusion.

For no apparent reason certain makes of cars have in certain years not proved very satisfactory in the hands of the public, even as certain vintages find no favour. Caution should be exercised in the purchase of vehicles which may have been used during the war period. There was nothing inherently wrong with those made at that time, but many of them were subjected to the roughest possible usage by bad drivers and under appalling conditions, and unless they had had a considerable sum of money spent on them they would be practically worn out in spite of being painted up nicely and looking smart.

It is difficult to give a general idea of the amount of wear that should be disregarded in testing second-hand cars for faults, nor is it easy to give the cost of repairs to make good defective or worn parts. The cost of a particular part might be 6d., but labour charges for fitting same might quite easily mount up to £10 according to the make of the car. The works of some cars, especially certain continental makes, are notoriously difficult to get at, and very often involves the taking down of an engine, gear-box, and clutch to replace a small part, in, for example, the clutch itself.

In conclusion, I can only emphasise again the fact that the prospective owner would be well advised to obtain the services of an expert before finally completing a deal. The small sum involved in an inspection fee may save him a very large sum in the long run.

INFECTIOUS DISEASES ABROAD.

THE following general summary is compiled from the monthly epidemiological reports published by the Health Section of the League of Nations, supplemented, when possible, by more recent information from other sources.

Plague.—A new outbreak of plague is reported from the Canary Islands, the affected localities being Santa Cruz and Realego Alto, both in the island of Teneriffe. These localities, as well as Las Palmas, Puerto Luz, and Orotava in the island of Gran Canaria, were also affected last year and in 1923, but little or no clinical or epidemiological information about the cases is available. In the Azores, cases continue to occur in the neighbourhood of Ponta Delgada in the island of St. Michael; of 20 cases reported up to Dec. 26th, nine were fatal. The apparent cessation of the epidemic at Lagos (Nigeria), reported in a previous summary,¹ lasted until the end of 1924, but six fresh cases occurred during the first 12 days of the present year, and the official declaration of freedom from the disease has been withdrawn. The outbreak at Los Angeles (California) is definitely at an end, but during the extensive search for infected rodents, which is being carried on

continuously there and elsewhere in California, as well as in other suspected areas in the United States, 63 infected rats were found at Los Angeles up to Jan. 3rd of this year, eight at Oakland between Dec. 13th and Jan. 3rd, and five at New Orleans up to Jan. 3rd. In South Africa cases of bubonic plague occurring singly or in twos and threes continue to be reported from rural districts of the Transvaal, the Cape Province, and the Orange Free State.

Cholera.—Excepting India, where, at present, cholera is somewhat more prevalent than during the same period of last year, very few cases of this disease have recently been reported from any part of the world.

Typhus.—No definite increase in the incidence of typhus is shown in the statistics recently received from countries of Eastern Europe. The latest information from Poland indicates that the prevalence of the disease in that country is steadily decreasing; the incidence at present in Latvia and Lithuania is also low in comparison with the incidence during the same period last year.

Small-pox.—The outbreak which occurred in Bosnia-Herzegovina in November, 1924, lasted only two weeks, during which 66 cases were reported. Most countries of Europe are at present unusually free from the disease. In Switzerland only two cases were notified during the first week of the present year.

Enteric Fever.—In nearly every country in the Continent of Europe, as well as in England and Wales,² a considerable increase in the recorded incidence of enteric fever was a notable feature of the statistics of disease during 1924 as compared with those of 1923. It may be that the increase can be partially explained by improved notification, but in general it was so considerable and widespread that a true increase of prevalence must be presumed. The increase was most marked in the Baltic region, particularly in Sweden, Finland, Esthonia, Latvia, and Lithuania, in each of which the number of cases recorded during 1924 was much higher than in either of the two preceding years. In Finland 499 cases were notified during October as compared with 280 in the same month of 1923, and 157 in the same month of 1922. From Russia recent statistics are not available except for the city of Leningrad, where 175 cases with 16 deaths were notified during the fortnight ended Nov. 1st, as against 98 cases with 12 deaths during the preceding fortnight. Germany, Poland, Bulgaria, and the Kingdom of the Serbs, Croats, and Slovenes are other European countries with an unusually high incidence of enteric fever during 1924. In Germany the weekly notifications began to decline after the middle of September, but in Poland the maximum had not been reached at the end of October.

Scarlet Fever and Diphtheria.—During the second half of 1924 there was a serious increase of scarlet fever in many areas of Russia, particularly in the chief cities. In Leningrad between the middle of July and Nov. 1st there were 1677 cases, of which 628 occurred during the last four weeks of the period. In Moscow, Kiev, and Odessa the incidence in September was twice as high as in August. Regions as widely separated as Gomel in White Russia, Velikij Usting in the north, Rostov on the Don, and Petrozavodsk near the Baikal Sea were affected, and it is said that the fatality-rate was high, and that severe cases amongst adults were frequent. In Scandinavia, Poland, the Netherlands and Germany scarlet fever was more prevalent during the last quarter of 1924 than during the same period of 1923, but in Jugo-Slavia and Bulgaria the incidence of the disease was relatively low. In most European countries the incidence of diphtheria at present is not higher than is usual at this season of the year.

¹ THE LANCET, Jan. 3rd, 1925, p. 43.

² In England and Wales approximately 4072 cases were notified during 1924 as compared with 3211 during 1923.

PATHOLOGY AND BACTERIOLOGY AT ST. BARTHOLOMEW'S MEDICAL COLLEGE.

NEW LABORATORY ACCOMMODATION.

THE teaching of pathology and bacteriology at St. Bartholomew's Medical College has recently been reorganised under the direction of Sir Frederick Andrewes. It now extends over two and a half years of the clinical curriculum, in order that the student may correlate his study of the science of disease processes with his practical observations in the wards. The transference last year of the department of physiology of the Medical College to its new building in Giltspur-street was timely, for it left vacant a

each 15 feet long, are placed one on each side of the lecturer's bench. An epidiascope stands opposite the lecturer's bench on a platform level with the back benches. Made by Zeiss, it is a combination of two of the latest models. It has a 30 ampère arc for episcopic projection, and by means of a revolving front will also show museum bottles on the screen, which is on the wall behind the lecturer's bench. Above the episcopic projecting apparatus is an optical bench on which a 5 ampère arc projects a direct beam either through a microscope or lantern slide. The lower power of this lamp makes it possible to leave slides on the screen for any length of time undamaged by heat. Sections or films can be successfully shown even under a 1/12 lens at a distance of 22 feet from microscope to screen.

Both in general plan and in detailed equipment this laboratory gives evidence of the most careful study of the needs of the student. While no expense has been

THE RECONSTRUCTED PATHOLOGICAL LABORATORY AT ST. BART'S.

laboratory adjoining the pathological block which has been recently adapted for the teaching of morbid anatomy and histology to large numbers of students. The enlargement was effected by the removal of the partitions which separated the private room of the professor of physiology from the main laboratory. The new room measures 63½ ft. by 36 ft., giving accommodation for 98 students doing practical work, allowing 3 feet for each, whereas for lectures, owing to the addition of seats in front of the first rows of benches, 200 men can be seated. A microscope lamp and a gas point are provided for each student, and one sink for every two students. The microscope lamps are made cheaply from inverted treacle-tins painted black outside and aluminium inside. The lids are screwed to wooden bases, and a hooded opening is made at one side of the tin. Each student has a locker under the bench behind him, so that he merely has to turn round to get at it. Lockers for men in the back rows are placed in nests on the walls. The benches are raised in tiers, each 5 inches above the one in front; the side benches are also raised. All the bench tops are teak, the rest of the wood being pine. Two demonstration benches,

spared in such structural alterations as the raising of the benches in tiers so that every student can see the lecturer, economy has been considered in so far that wherever possible the fittings and bench tops of the old laboratory have been adapted and fitted in the new one. The result is a very fine laboratory, light and spacious.

PRESENTATION TO PROF. MATTHEW HAY.—The town and University of Aberdeen recently combined to honour one who has rendered signal service to both. On Jan. 14th Prof. Matthew Hay was presented with his portrait in oils by Mr. Charles Sims, R.A., Keeper of the Royal Academy. Principal Sir George Adam Smith on behalf of the University, and Lord Provost Meff on behalf of the town paid warm tribute to the work of Prof. Hay, who occupied the chair of forensic medicine in the University since 1883, and who was medical officer of health for the city from 1888 to 1923. Some indication of Prof. Hay's untiring industry may be gained by recalling that, apart from these offices, he was an original member of the Medical Research Council, and represented the University on the General Medical Council, the Carnegie Trust, and the Federated Superannuation Fund. For 25 years he was chairman of the University's finance committee.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

The Quality of the Vienna Milk-supply.

At a recent extraordinary meeting of the Vienna Paediatric Society the problem of the supply of children's milk for the Vienna population was discussed by medical men and agriculturists. Prof. Pirquet opened the meeting with a report on the relative value of milk as food, showing that it is the cheapest source of animal albumin. The rearing of milch-cows must be regarded as more economical than the rearing of pigs). One unit of feeding material is turned into two-thirds of a unit of milk, whilst the latter-named animals give only a return of one-third of human food unit. Dr. Reichel showed the present condition of the Vienna milk-supply as regards quality. The data given by him were collected last year by private enterprise to obtain an exact picture of the actual conditions with a view to legislative measures. The following points were those chiefly investigated: Adulteration, decomposition, denaturalisation of milk, and the health of the animals. The result was disappointing. The milk supplied to Vienna children was manifestly poor in fat and with a high bacterial content. The production and manipulation of milk was conducted on a very low standard of cleanliness. Since 1909 private enterprise had endeavoured to secure first-class children's milk, but the public authorities had not done anything in this respect. Mr. Winkler explained that if milk was to have a low bacterial content (not more than 80,000 in a cubic centimetre) and to be free from all pathogenic material, it must be obtained from healthy cows and handled only by healthy and cleanly persons. Dr. Schlossmann emphasised the necessity of sending all milk required for infant consumption through a central control station in the cities, where it can be stored (cold storage) and treated in any way necessary. The price of milk must be in proportion to the costs of production and transport, otherwise the supply drops short of demand. This was demonstrated by Mr. Hainish, the President of the Austrian Republic, one of our largest agriculturists, who also took part in the discussion. He said that before the war 850,000 litres of milk were brought daily to Vienna. When the price was fixed at a low sum by the magistrates the supply fell to 60,000 litres. Our republic has sufficient facilities to enable every inhabitant to get at least one litre of milk per day out of the production of the country without relying on imports.

A Hygiene Exhibition in Vienna.

In early summer an exhibition devoted to hygiene will be held in Vienna. The well-known museum of hygiene in Dresden will coöperate and a most comprehensive exhibition may be expected. A series of dry and wet specimens, objects, models, tables, and statistic and graphic demonstrations will be on view. A special department will deal with modern individual hygiene, the supply of sound and economic food, including various diet formulæ for the normal and diseased body, and vegetarianism; healthy housing, clothing, and physical culture (and scientifically conducted cosmetic culture) will also be demonstrated. Another department will be devoted to the vast subject of social hygiene; antenatal and infant welfare, the care of the chronically diseased tuberculous subjects and cripples, as well as of juveniles and of the senile will receive attention. Sections will be devoted to: modern sport and gymnastics; the prevention of infectious diseases, including venereal diseases; the problems of city buildings, drainage, police, water-supply; control of food; the protection of the manual and brain worker against the dangers involved by their occupation; the training of nursing personnel; the organisation of spas and sanatoriums, of public and private hospitals, to which the State corporations and private institutions will be able to contribute. The intoxicating liquors and habit-forming poisons (alcohol,

morphine, cocaine, arsenic) form another section. The problem of recreation—chiefly from the viewpoint of the poorer classes, who cannot afford a regular week-end or a few weeks stay in the country—will receive attention. The Municipality of Vienna deserves credit for providing huge sun-baths, playgrounds, and forest or open-air schools for debilitated children. A series of lectures by eminent physicians will aid the public in obtaining an insight into the modern views of hygiene. In connexion with this exhibition the united organisations of Austrian women will conduct an exhibit, "the new household," devoted to the reorganisation of the antiquated methods of housekeeping and cooking. This will be the first of its kind in Europe. Its aim is to open up the problem as to how all requirements of the family can be satisfied at a minimum expenditure of money, mental and manual exertion and time. The reduction of household work by time- and labour-saving devices and machines will give the housewife much greater opportunities of rest and spells better health.

Austrian Red Cross Society.

At a recent meeting of the Austrian Red Cross Society Mr. Beck, the President, pointed out that now the chief line of work was directed towards the propagation of peace-time enterprise. The problem of sanatoriums for consumptives, of training of qualified nurses, as well as the aid of public and private charitable institutions was now receiving special attention. Without the financial and moral help by the Red Cross many of these institutes would have been completely ruined during the last few years. The large stores of provisions, sanitary appliances, and outfit at the disposal of the Society were used to keep these institutes running. The large tuberculosis hospital in Grimmerstein is conducted solely by the Society, and here hundreds of diseased women and children are restored to health. In the last months of the year 1924 attention has been centred chiefly in the work of social care of young people, and the efforts made to interest the younger classes of the population in this work have met with very satisfactory results.

Jan. 14th.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

Outbreaks of Typhoid Fever.

It is more than ten years since New York City was visited with an explosive outbreak of typhoid fever, such as began in the third week of November last. In the week ending Dec. 13th, 1924, 116 new cases were reported to the health department, and since then a score or so of new cases have appeared daily. Over 400 cases have occurred during the outbreak. Typhoid fever has also been prevalent in the adjoining counties of New York State and in the city of Chicago, where there have been 99 cases with 11 deaths. The source of contamination remains more or less of a mystery. The cases are scattered widely over the area of the city, and yet careful investigation of the water- and milk-supply have failed to discover any loophole for infection. Suspicion has fallen upon some of the oyster beds, since a large proportion of the cases admit having consumed oysters. Although no *B. typhosus* has been found amongst the oysters, and the case against them is at least unproven, the Health Commissioner, Dr. Frank J. Monaghan, has put a ban on the sale and distribution of shell-fish from beds in Hempstead Bay. The special appropriation of \$50,000 which the city has made for combating the outbreak represents a mere fraction of what the oyster industry must be losing. An appeal for help has been addressed to the Federal Health Service, which responded promptly. The investigation has been assigned to Dr. L. L. Lumsden, who has already been successful in finding the origin of several typhoid epidemics in different parts of the country. He will be

assisted by several junior officers of the Service, and there is reason to believe that the investigation will prove of first-class importance to the science of epidemiology.

Social Values of Disease.

In a De Lamar lecture at the School of Hygiene, Johns Hopkins University, on Jan. 12th, Dr. Homer Folkes discussed public health in relation to social welfare. He stressed a point of difference between the medical practitioner and the health officer in that the former responds equally to all calls for help, whereas the latter is compelled by circumstance to select a few diseases upon which to concentrate his effort and financial resources. A disease which carries off babies in the first year of life is obviously of less social significance than a disease which slays the young parent of either sex leaving children uncared for or unprovided for according to whether the mother or the father is carried off. From this point of view the age-group 25-35 is, perhaps, the group most to be protected from mortality. From a more strictly economic point of view the group 20-30 is of first importance. The requirements of the American social ideal involve an increasing investment in the citizen during the first 20 years of life, and it is only in the third decade that the returns begin to come in. Besides, the consideration of mortality is that of the degree of recovery in cases which do not terminate in death. Although four diseases—heart disease, cancer, Bright's disease, and pneumonia—have now passed tuberculosis as causes of death at all ages, only pneumonia can compare at all with tuberculosis as a cause of mortality in the third to fourth decades of life. Moreover, we have no means as yet of controlling the mortality from pneumonia. There are two other diseases in still more humble positions in the tables of mortality which are of great social significance. These are mortality in childbirth and syphilis. The first is really a notable cause of death when the deaths are measured against the total population exposed to risk, while the second parades under many disguises, and if all these were collected under a single caption there is no doubt that an important cause of death would be revealed. Besides the social significance of a disease, the practical administrator must also take into account the scientific knowledge at our disposal for combating it, the practicability of applying that knowledge, and the significance of the disease, not only to the present generation but also to posterity.

The Journal of Scientific Instruments, a monthly publication dealing with the principles, construction, and use of their apparatus, is produced by the Institute of Physics with the co-operation of the National Physical Laboratory; the journal has been published hitherto by the Institute, but in future will be issued from the Cambridge University Press on behalf of the Institute.

THE NEW MEAT REGULATIONS.—The Minister of Health has addressed a letter to Lord Banbury and Sir Henry Cautley, who consulted him as to certain prevalent misunderstandings of the Public Health (Meat) Regulations, 1924, and the Rural District Councils (Slaughter-houses) Order, 1924. (See *THE LANCET*, Jan. 10th, p. 90.) These Regulations, the Minister writes, are designed to give effect to certain of the recommendations of the Departmental Committee on Meat Inspection, and do not impose any limitation as to the persons who may slaughter animals or as to the places at which animals may be slaughtered. What they do require is that where an animal is slaughtered for sale for human consumption notice must be given to the local authority, and the carcass must be retained for a few hours to give the inspector an opportunity of inspecting it if the local authority desire that this should be done. This is a very important provision for preventing traffic in diseased meat, inasmuch as inspection can only be satisfactorily carried out at the time of slaughter when all the organs are available for examination. This provision only applies where the meat is intended for sale, and the requirement as to the retention of a carcass does not apply in the case of a sheep, the danger of disease in sheep being relatively small.

"Audi alteram partem."

THE SALE OF PATENT MEDICINES.

To the Editor of THE LANCET.

SIR,—The publication of a Special Supplement on the Sale of Patent Medicines by *THE LANCET* of Jan. 10th has again brought an important subject to the notice of the medical profession. This Supplement, which contains the report of the Select Committee of the House of Commons on Patent Medicines, 1914, and the text of the Proprietary Medicines Bill, 1920, deserves careful perusal by every medical man. While all are aware of the harm which is caused by the indiscriminate sale of patent medicines many are still unaware of the extent of the evil and of the powerlessness of the law to deal effectively with it. Ample information on both of these subjects is supplied by the report. It must be more generally recognised that the present uncontrolled sale of remedies and appliances, which are vaunted for powers they do not possess, leads many unfortunate sufferers to lose valuable time at the onset of serious illness before they seek medical advice and treatment. The analysis of many of these secret remedies has shown that they are useless and cruel frauds sold at an exorbitant price. There is urgent necessity for amendment of the present law. If the Proprietary Medicines Bill, 1920, became law it would go far to remedy the present deplorable state of affairs. It is greatly to be hoped that the present Government may be induced to bring about this very necessary reform so that we may at any rate no longer lag behind our colonies and other countries in a matter so vital to the health of the nation.

I am, Sir, yours faithfully,

Manchester, Jan. 26th, 1925. GEORGE R. MURRAY.

To the Editor of THE LANCET.

SIR,—If the public is concerned about its own interests, it should be deeply grateful to *THE LANCET* for bringing back to life the report of the Select Committee of the House of Commons on Patent Medicines. I trust that as a result of *THE LANCET*'s public-spirited action the present representatives of the public at Westminster will be moved to give their earnest attention to the striking statements of this plain-spoken document, and see that legislation upon the urgent questions it raises is not further delayed. That it was shelved during the Great War was perhaps inevitable; that a measure founded on the report got no further than the Upper House during the political turmoil of the last few years was not surprising; but now that we have entered on quieter times and there is no general election in immediate prospect, the House of Commons, one may hope, will have more ample opportunity for undertaking legislation of the kind that is useful rather than showy.

Of the urgent need of legislation on the subject in question I think no one who studies your re-issue of the report can doubt. We find the Committee roundly asserting, in sum, that under cover of a legitimate trade in medicinal preparations the varied resources of advertising were being employed in the promotion of a number of impudent and heartless frauds, involving danger to life and health as well as to purse; that these frauds were being prosecuted by the help of mendacious assertions, bogus testimonials, and fictitious signatures; that highly intoxicating beverages were being puffed and sold as medicines without any indication of their alcoholic contents; that advertisements were issued which were thinly veiled incitements to criminal acts; and that the large sums spent in advertising were sufficient to keep a large section of the press muzzled on the whole subject. Add to this that ours seemed to be about the only civilised country that had made no

serious attempt to check such abuses, and that even the few enactments bearing on this traffic were rendered abortive by the failure of the legislature to provide for carrying them into effect, and the case for the prompt re-introduction of the interrupted Bill of 1920 seems unassailable.

At the present day, fortunately, medicine is not unrepresented in the legislature; and it is to the medical Members of the House of Commons, and to the representatives of the more modern universities, who number so many medical men among their constituents, that appeal may in the first instance be justifiably made.

I am, Sir, yours faithfully,

The Athenæum, Jan. 24th, 1925. ISAMBARD OWEN.

To the Editor of THE LANCET.

SIR,—Your supplement of Jan. 10th will, I am sure, be of more than passing interest to the profession and the public by exposing the menace to the health of the community by the use of proprietary medicines and the fortunes made by the sale of them to an over-credulous public.

The object of this letter is to illustrate the way in which some at least of the pretensions of those who batten on human suffering may be checked by individual effort. About ten years ago there appeared at the end of a number of a well-known monthly magazine of high repute a concealed advertisement having the likeness of an editorial article, occupying two pages—a plausible reference to a cure for consumption, concluding with an address in Australia to which £5 was to be sent for particulars of the remedy. I at once wrote to the editor, calling his attention to the article, urging him to see that this masked advertisement did not appear in future numbers, at the same time pointing out how derogatory it was for a journal of such standing to become party to a fraud. To secure the success of my protest I promised, in the event of the "article" being repeated, to ask my colleagues to remove his magazine from their waiting-room tables. I received a "high and haughty" reply, together with an invitation to wait upon the editor. I then wrote suggesting an interview at my house. This concluded the correspondence, but its object was achieved in that no further veiled advertisements appeared.

I am, Sir, yours faithfully,

CHARLES W. CHAPMAN.

Wimpole-street, W., Jan. 13th, 1925.

DRUNK OR SOBER?

To the Editor of THE LANCET.

SIR,—We have read with interest and amusement the address of Sir James Purves-Stewart delivered on Jan. 13th before the Society for the Study of Inebriety. At the same time we must confess to a certain feeling of disappointment; for we had hoped that the harassed divisional surgeon might, perhaps, derive from this lecture valuable assistance in the most thankless and difficult of all his tasks—something a little more helpful, for instance, than a half-hearted instigation to the performance of lumbar or cistern puncture! And there is one point on which we must at once join issue with Sir James Purves-Stewart—namely, his suggestion that "the police surgeon may be too open to suggestion." We venture to submit that the police surgeon is very much less open to the charge of bias than is the medical man called in by the suspect for the express purpose of proving the latter's sobriety. With a long experience of many police divisional surgeons, we have no hesitation in saying that we have implicit confidence in their absolute impartiality. The divisional surgeon has nothing to gain by supporting the provisional diagnosis of the arresting police officer; in point of fact he very frequently reports on his man as being sober, and we are satisfied that when the divisional surgeon has any doubt as to the prisoner's sobriety, the prisoner gets the benefit of the doubt.

We also contend that a police surgeon attached to any of the big stations in central London has an unrivalled experience in the recognition of inebriety in all its stages, and, for ourselves, we would prefer to rely on the opinion of such an experienced and impartial observer rather than on that of any other medical man, however eminent in his own particular line. Again, we do not feel that Sir James Purves-Stewart has sufficiently emphasised the notorious fact that drunkenness may be a very transient phenomenon. We can most of us recall incidents in the course of bump-suppers, or similar festivities, illustrative of this point—e.g., the incoördination and dysarthria of the undergraduate at 10.30 P.M., who has pulled himself together and is conversing amicably, though possibly with a slightly overdone solemnity, with the dean at 11.15 P.M. The same sort of thing occurs not infrequently at the police-station, if we substitute a distinguished consultant for the dean of the bump-supper days.

We are, Sir, yours faithfully,

CHARLES A. BALLANCE.

London, Jan. 26th, 1925. MAURICE CASSIDY.

ETHYLENE GAS.

To the Editor of THE LANCET.

SIR,—Dr. Langton Hewer's article in your issue of Jan. 24th on his investigations as to the value of this anæsthetic are of interest, and all anæsthetists will, I am sure, be grateful to him for publishing them. Undoubtedly with oxygen it is most valuable. Unfortunately there is a fly in the ointment; I exclude the difficulty in compressing the gas, as seemingly Messrs. Coxeter have overcome that; personally the chemist who most kindly attempted to do so for me some 20 months ago was not as successful. The one point which does, however, interfere with the value of this anæsthetic is its explosive nature. Now that electric sterilisers are more popular, this contra-indication to its general employment may not be as powerful. Still, I would emphasise the fact that its use in the neighbourhood of a naked light is fraught with danger.

I am, Sir, yours faithfully,

CHARLES T. W. HIRSCH.

Hyde Park Gate, S.W., Jan. 25th, 1925.

ALASTRIM, PARA-SMALLPOX, AND VARIOLA.

To the Editor of THE LANCET.

SIR,—Prof. Jorge appears to deal with his subject very fully, but I do not think the Gloucester cases of last year fitted altogether with his description. (1) *Age-distribution*. The majority of the cases occurred in children, the greatest incidence being between the ages of 5–15. (2) *Onset*. In every case I have seen there has been a definite prodromal illness of three to four days, frequently severe. (3) *Rash*. Distribution was similar to severe small-pox, and in marked cases there were lesions with umbilication and scarring. In my experience there was, contrary to Prof. Jorge's findings, a definite relationship between local and general conditions. A severe rash was always accompanied by a certain amount of prostration and frequently by secondary fever. I fail to see how it would be possible to differentiate between a well-marked case of so-called alastrim and a mild case of true small-pox.

Material from some of our cases at Brockworth was sent to Dr. M. R. Gordon at the Pathological Department, St. Bartholomew's Hospital. He reported (1) the serological reaction obtained from the material was similar to that from vaccine lymph, and (2) the material he received from a very virulent case in the Surrey area in the autumn of 1923 reacted serologically in the same manner as the Gloucester strain.—I am, Sir, yours faithfully,

RONALD B. BERRY,

Jan. 24th, 1925. Medical Officer of Health, Gloucester.

"ELECTRONIC REACTIONS."

To the Editor of THE LANCET.

SIR,—One sentence of a certain report quoted in the last issue of THE LANCET (p. 180) is very illuminating. The signatories to the report presented to the joint Sections of Medicine and Electro-Therapeutics of the Royal Society of Medicine declare that "the fundamental proposition underlying the original and other forms of apparatus devised for the purpose of eliciting the so-called electronic reactions of Abrams is established to a very high degree of probability." (It should, perhaps, be noted that in the *British Medical Journal*, the word "designed" appears in place of "devised.") But how was this fundamental proposition first arrived at? Surely, nothing could have been known about the electronic reactions prior to the construction of the apparatus designed or devised to elicit them? We must therefore conclude that the electronic reactions were first conceived in Abrams' bosom, then demonstrated or elicited by an ad hoc apparatus, designed or devised to elicit them, but which (we are now assured) had no business to elicit them, and, finally, have been elicited by an ad hoc contrivance devised or designed by Dr. Boyd to elicit them.

In other words, the apparatus of Abrams and of Boyd are not scientific arrangements designed or devised to amplify or utilise experience, but are contrivances designed or devised to satisfy a wish present to the mind of the inventors—namely, the wish to elicit the "reactions of Abrams."

Nothing is more certain than that any contrivance designed or devised to elicit physical phenomena, of a kind never experienced but simply imagined, will either (1) fail to satisfy the wish of the inventor, or (2) if it does apparently satisfy his wish will owe its seeming success to the operation of some factor which, consciously or unconsciously present to the mind of the inventor, escapes detection by trustful "investigators." This is axiomatic, and of immense importance in these affairs. In the case of an investigation, conducted in France during the war, by a small committee, of which I was a member, it became very clear that the inventor (who claimed to have worked under Abrams) had, at an early stage, and prior to all experience, become possessed by the wish to invent a wonder-working machine that would do certain things, the like of which had not until then been done. And the precocious obsession by such a wish can always be detected, whether we have to do with getting gold from the sea, petrol from tap-water, cucumbers from moonshine, or ectoplasmic limbs from a medium.

But there is another axiom. In all such cases a stage is reached at which investigators are asked (and sometimes join in asking) that personal assurances of good faith should be allowed to take the place of the production of such evidence as is needed to substantiate the claims made, and as could be furnished, were the claims substantial. When this demand is made the province of science has been left behind, and we enter a domain in which demonstrations of confidence are confused with proof of integrity.

In the case of Dr. Boyd's contrivances, we are asked, by the signatories to the report, to accept assurance as to the critical judgment of the research officer to the Society of Psychical Research in place of the *experimentum crucis*! Mr. Dingwall, I know, will not be surprised if I say, frankly, that I like not the security. And I am sure that Mr. Dingwall himself will not accept the proposition that faith in his negative findings should exempt men of science from the performance of a scientific duty. I am reminded of some delightful passages in the late Dr. Geley's last work. After assuring his readers of the perfect control always instituted during certain spiritualistic performances, he declares that, on one occasion, when some very beautiful manifestations were obtained, the controls were omitted, owing to the lively emotions sustained by the investigators. But this, says Dr.

Geley, was of no importance. The beauty of the results firmly sustained the belief of the investigators in the good faith of the medium, a belief otherwise warranted by the institution of most rigorous controls on occasions when the results were negative!

Indeed, in all these situations the same *lacunæ*, the same excuses, and the same assurances return with almost calculated regularity. These recurrences, these *lacunæ*, do not authorise us to suggest fraud. But they do compel us to declare that, when they are present, the methods of scientific inquiry have not been followed.

Abrams began his career by performing a real service when, many years ago, he demonstrated his "lung reflexes." The sad comedy developed afterwards. That certain changes in percussion notes do occur in response to certain variations in muscular and visceral tone is now generally accepted. But, of any connexion between unseen bottles in hatches and changes in the percussion notes obtained over a little boy's belly, one can only say: *De non apparentibus et de non existentibus eadem est ratio*.

I am, Sir, yours faithfully,

F. G. CROOKSHANK.

Wimpole-street, W., Jan. 23rd, 1925.

BLOOD CHANGES IN SPRUE AND PERNICIOUS ANÆMIA.

To the Editor of THE LANCET.

SIR,—In his interesting paper which appeared in your columns on Jan. 16th (p. 75), Dr. C. Elders concludes that the blood picture of sprue cannot well be distinguished from that of pernicious anæmia, in respect particularly to its high colour-index so characteristic of that disease. The 12 blood counts in two cases of sprue which he records gave a colour-index above the normal—1.0—in no fewer than ten counts, was normal in one, and below normal in one, the average index being 1.2. The six counts in a case of pernicious anæmia gave an index above normal in all counts, the average being the unusually high one of 1.57, and the first count giving the extraordinary index of 2.4.

In view of other features of similarity presented in the two diseases these high figures of colour-index, if correct, are striking; and I therefore ask permission to say that they appear to me to require some further consideration and elucidation before any final judgment is based upon them. I desire to point out, that in all the 18 counts recorded the figures of colour-index given are as much as one-fifth to one-third higher than the actual colour-index yielded in the usual way by the percentages of hæmoglobin and of red cells given or obtainable from the data in the reports.

Thus, in the first count recorded, the figure of hæmoglobin—20 per cent.—divided by the percentage of red cells—viz., 980,000, or 19 per cent. of the normal 5,000,000—yields a colour-index practically normal, viz., 1.05; whereas in the report the colour-index for this count is given as 1.3. And similarly in all the other counts. When these are corrected the results as regards colour-index are very different from those stated in the reports. It then appears that in the two cases of sprue, instead of a colour-index above normal in ten out of 12 counts, it was above normal in only three counts, normal in one count, and below normal in no fewer than eight counts, the average being 0.97 instead of 1.2. On the other hand, in the case of pernicious anæmia the colour-index was above normal in four out of the six counts, and below normal in the other two; but the average was 1.28 instead of the unusually high one of 1.57.

Of all the blood changes in the disease pernicious anæmia, the most constant at all stages of the disease, in my experience of about 1000 counts in 200 cases, is a colour-index above normal, found in my cases in 83 per cent. of all blood counts, normal in 7 per cent. of counts, and below normal in only 10 per cent. of counts; average, 1.16. On the other hand, in all the

other cases of severe anæmia presenting degrees of blood change sometimes as low as 14 per cent. of red cells, comparable in degree or character with those of pernicious anæmia, the colour-index is found above normal in only 12 per cent. of counts, normal in 28 per cent., and below normal in no fewer than 60 per cent. of counts; average, 0·8.

This is the class of case which I have differentiated and term septic anæmia. Judged by these data, the anæmia of cases of sprue of the kind now recorded belongs to the class of anæmia of septic type, rather than to the class constituted by the great hæmolytic disease known by the name of pernicious anæmia.

I am, Sir, yours faithfully,

WILLIAM HUNTER.

Harley-street, W., Jan. 20th, 1925.

AIR-EMBOLISM FOLLOWING URETHROSCOPY.

To the Editor of THE LANCET.

SIR,—By a curious coincidence there appear in both *The Lancet* and *British Medical Journal* of this week (Jan. 17th, 1925) notes of cases of air-embolism following urethroscopy; the one by Mr. R. S. Roper, the other by Mr. K. V. Trubshaw. Attention is very properly drawn by both these surgeons to the dangers of aero-urethroscopy. I have myself had three cases of what I believe to have been air-embolism following urethroscopy, one of which, unfortunately, proved fatal.

(1) About 20 years ago, shortly after I was appointed assistant surgeon to the Royal Victoria Hospital, Belfast, I was examining in the out-patient department the urethra of a young adult male with Fenwick's aero-urethroscope, when the patient suddenly became rigid and appeared to be about to have an epileptic fit. The urethroscope was immediately removed and the symptoms passed off in a few minutes, leaving no after-effects.

(2) On June 1st, 1923, I was examining a man, aged 45 years, in my consulting-room. The patient had a stricture in the bulbous portion of the urethra, through which I could only just thread a filiform bougie. After removing this bougie I passed the tube of a Wyndham Powell's urethroscope, and proceeded to distend with air. While I was inspecting the urethra the patient took an attack of dyspnoea and complained of pain in the left mammary region. He became faint, with a slow and feeble pulse. The tube was immediately removed and the symptoms passed off in a few minutes. Previous to this examination the patient had had filiform bougies passed, and since then has had an internal urethrotomy performed, and large metal dilators passed at regular intervals without any symptoms whatever.

(3) The third case was that of a stout, florid man, aged 67, with an impassable stricture. On Feb. 5th, 1922, I went some miles into the country to operate on him in the local hospital. Before the anæsthetic was administered I tried to pass a fine filiform bougie without success. This was followed by slight hæmorrhage. I now introduced the tube of a urethroscope which fitted rather tightly into the urethra. Air was being pumped in when we noticed that the patient was breathing stertorously, and had become cyanotic and unconscious, with dilated pupils and loss of corneal reflex. Notwithstanding all efforts to restore him death took place in a few minutes. A post-mortem examination was not allowed. If the anæsthetic had been given the death would have been wrongly attributed to it.

Now that attention has been drawn to this matter surgeons will be on the look-out for the first signs of distress in a patient undergoing an examination with the urethroscope, and may, perhaps, be warned in time to withdraw the instrument before serious symptoms have developed. Mr. Roper discusses the question of urethral shock and refers to cases occurring in St. Peter's Hospital. Thomson-Walker¹ faithfully records three cases which were under his care, two of which proved fatal. In all, a stricture was present, and in all the urethra had been examined under air-distension. The post-mortem examination of the fatal cases does not seem to have raised the question of air-embolism. It would be interesting to

¹ Genito-Urinary Surgery, Cassell and Co., 1914.

know if the brain was examined, as some of the symptoms in the recorded cases would seem to point to cerebral involvement.

We have now had sufficient experience of this accident to emphasise the importance of not using air-distension if any bleeding is present. It is also well to keep a close watch on the patient's condition, and instruct him to call out at once if he feels the slightest distress apart from the local discomfort of instrumentation. I wonder if urethral shock really occurs, and, if so, is it ever fatal. During many years of practice I have never seen anything beyond the faintness which any manipulation may produce in a patient who is frightened or nervous, except the alarming symptoms occasionally produced by the introduction of cocaine into the urethra, and directly attributable to the drug. The advantages of aero-urethroscopy are so obvious that there can be no question of abandoning it, but the risk of air-embolism must now be borne in mind.

I am, Sir, yours faithfully,

ANDREW FULLERTON,
Professor of Surgery, Queen's
University of Belfast.

Jan. 19th, 1925.

PICRIC ACID FOR BURNS.

To the Editor of THE LANCET.

SIR,—I am glad to see that Mr. H. S. Souttar, in his article on Burns and Scalds (*THE LANCET*, Jan. 17th), calls attention to the dangers of picric acid applications and has given up its use. I have never employed picric acid for burns and scalds, as I have found other methods more satisfactory. On several occasions I have seen very unpleasant complications result from picric acid; judging from my own observation, I do not think that medical men always realise that picric acid is tri-nitro-phenol. It is the phenol element that is poisonous, especially in little children.

I am, Sir, yours faithfully,

GEORGE PERNET, M.D.
London, W., Jan. 26th, 1925.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdr. J. Martin is placed on the Ret. List, with the rank of Surg. Capt.
H. A. M. Whitby to be Surg.-Lt.

ROYAL ARMY MEDICAL CORPS.

Capt. J. W. Malcolm is granted the local rank of Maj., for serv. with the Iraq Levies.

TERRITORIAL ARMY.

Lt.-Col. H. G. G. Mackenzie, having attained the age limit for retention, relinquishes his commn. and retains the rank of Lt.-Col.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Lt.-Col. C. A. Lees, having attained the age limit, is retired, and retains his rank with permission to wear the prescribed uniform.

ROYAL AIR FORCE.

J. MacC. Kilpatrick is granted a short service commission as a Flying Officer.

Lt. V. P. Ellis, Dental Surgeon, General List, Army, is granted a temporary commission as a Flying Officer on attachment to the R.A.F.

INDIAN MEDICAL SERVICE.

Major Kunwar Shamsher Singh has handed over the duties of Superintendent of the District Jail at Rawalpindi to Lt.-Col. M. Corry and Lt.-Col. N. M. Wilson, the District Jail at Ambala to Major B. Gale and Lt.-Col. H. C. Keates, and the District Jail at Lyallpur to Lt.-Col. R. T. Wells. The Governor of Bihar and Orissa has nominated Col. H. Ainsworth to be a member of his Legislative Council.

The King has approved the relinquishment of his temp. commission by Lt. Shanker Lal Gupta.

Obituary.

SIR JAMES MACKENZIE, M.D. EDIN.,
F.R.C.P. LOND., F.R.S., LL.D. ABERD.,

CONSULTING PHYSICIAN TO THE LONDON HOSPITAL; DIRECTOR,
INSTITUTE OF CLINICAL RESEARCH, ST. ANDREWS.

WE regret to announce the death of Sir James Mackenzie which occurred at his London residence on Monday last.

Sir James Mackenzie was born in 1853 at Scone, where his father, Robert Mackenzie, resided. He received his early education at the Perth Academy, whence he proceeded to the University of Edinburgh as a medical student. After graduation in 1878 he held the house appointments at the Royal Infirmary of Edinburgh, immediately after which he studied for a short period in Vienna, and then migrated to Burnley, where he went into general practice and where he remained for nearly 28 years. He was a highly equipped man with a scientific outlook from the first, and it was in the conduct of his practice that he made close written observations upon signs and symptoms in his various cases which led eventually to his commanding position as a cardiologist.

But it was long before his researches yielded anything in the nature of a general message to science, and those who have followed his career know that the time which he spent in collecting and collating notes and verifying conclusions would have terrified a man less nobly absorbed by his double determination to arrive at truth and to do good. He has told us that he became in an early stage of his career as a doctor specially interested in the nature of heart affections because the symptoms from which the conditions had to be inferred were few in number, enabling investigations to be limited and comparisons to be instituted along definite lines. Gradually there unfolded before him the great design to clear up some of the obscurities darkening our knowledge of cardiac mechanism and our interpretation of cardiac symptoms, and, where possible, to bring organic changes in the heart into relation with the symptoms, ascertaining their significance in respect both of prognosis and treatment. Steadily, and undeterred by the exhausting routine of general practice, he pursued his observations of cardiac mechanism along original lines and by original methods whose efficacy was due greatly to the intensive watching of individual cases over long periods, for from the beginning Mackenzie felt that if the generally accepted foundations of cardiac therapeutics were to be labelled as insufficient or unsound, unimpeachable evidence must support the challenge. He recognised, of course, as everyone must, that much of the orthodox treatment of heart disease which held the field till 20 years ago was correct, but he saw also that routine was often employed which would only be useful in certain cases, and that the vital importance of many trivial signs indicating cardiac irregularity had passed unnoticed. His close study of these irregularities soon threw light upon functional derangements of the heart in an amazing manner, and further gave indications both for logical diagnosis, prognosis, and treatment. The arrhythmias and the manner in which the heart responds to the varied conditions that may be brought about by infectious diseases or by the exhibition of drugs were made the subjects of special research, and at length the minute and assiduous investigations carried on for many years began to obtain recognition, and as each contribution to our learning was published new adherents were gained.

While still at Burnley he published a notable work, "The Study of the Pulse," and made good some of his conclusions which had been considered speculative when first promulgated; but probably his labours were first made clear to anything like a large audience at a meeting of the British Medical Association at

Toronto in 1906. On the voyage to this gathering our representative noticed how in a circle, which included also Henry Ashby, Clifford Allbutt, and Sims Woodhead in particular, Mackenzie's colloquial demonstrations of the bundle of His and reflections on similar sides of his deeply thought-out views, would cut right across text-book instruction, and yet appear convincing in their logicity; and when he read his contribution those who had heard his preliminary and informal disquisitions were not surprised at its effect. Prof. Aschoff opened the discussion, which centred around heart-block, with a description of the anatomical-pathological basis of irregularities and failure of heart muscle, the result of investigations

SIR JAMES MACKENZIE.

made by himself and Dr. Tawara upon the intracardiac muscles. This formed an excellent prelude to Mackenzie's paper, which described with full illustrations the phenomena of heart-block. He showed how his conclusions had been arrived at by the personal following-up, over 20 years or more, of groups of cases, tracing the association of the signs and symptoms—especially pain—with the passage of time, with the general conditions of the patient, and with accidental circumstances, and indicating his method employed for detecting and standardising intracardial lesions. He pointed out that the stimulus for contraction from auricle to ventricle through the bundle of His, if depressed, will result in a prolongation of the interval between auricular and ventricular contractions, until the ventricular systole may drop out or respond irregularly to auricular beats. He then explained the methods which he had devised for appreciating affections of the bundle.

Recognising that in cardiac disorder it is necessary to obtain information in regard to the movements of the different chambers of the heart, he devised instruments convenient for the purpose by modifying the sphygmograph so that simultaneously with a radial tracing the record of other movements connected with the circulation or respiration could be noted. He laid down that the essential requisite for

the interpretation of the tracings of any movements of the circulation is a standard by which different phases of cardiac revolution can be recognised, and, taking the radial pulse as that standard, its cause being known and its position in the cardiac cycle being fixed, he was able to record any movements occurring before, with, or after the radial pulse, and refer them to forces having a definite period in the cardiac cycle. He produced graphic illustrations of simultaneous tracings of the carotid and radial pulses, showing the duration of the interval between them; and also simultaneous tracings of the apex beat and the radial pulse, and of the apex beat and the jugular vessels and the radial pulse, while by other tracings he illustrated graphically the influence of rest and of depressing disease, as well as of vagus stimulation and of the various phenomena of heart-block.

In 1907 he came to London and took up consultative practice. He was immediately appointed lecturer in cardiac research at the London Hospital and elected physician to the institution, and in the following year brought out a large and carefully illustrated volume entitled "Diseases of the Heart," which had a great reception and went through several editions in a comparatively short space of time, being also translated into German, French, and Italian. The long years of waiting were triumphantly rewarded by private practice in overwhelming quantity and unstinted official recognition. In 1911 he delivered the Oliver-Sharpey Lectures before the Royal College of Physicians of London, in which he reviewed the whole subject of heart failure, forming a penetrating comparison between the old and the modern conceptions. The lectures were published in full in THE LANCET, and did not escape criticism in detail, for researches had been made since his earlier work, with which all are now familiar, and which necessitated, perhaps, more variations in his views than he was prepared to allow; but the enormous value of the researches that he had pursued steadily for a working generation was acclaimed on all hands.

During the war Mackenzie played a prominent part in assisting the authorities to evaluate heart disease as structural or functional, and as temporary or permanently incapacitating its victims. He was appointed physician to the King in Scotland, in 1915 he was knighted, and in 1916 was elected F.R.S. But at the cessation of hostilities, and when at the zenith of his fame, he closed down all his metropolitan work and went to St. Andrews, where he founded the Clinical Institute, with the broad intent to bring the methods of general practice into touch with the methods of research. There he worked steadily for four years in close touch with his collaborators, and the outcome of some of their labours has already been published widely. The tribute from his St. Andrews colleagues, which Dr. David Waterston sends, explains what it must have meant to Mackenzie to leave London, and suggests the wide scope of his final interests.

About a year ago he became by a tragic coincidence the victim of the cardiac affection which was the subject of his last written work, for he died of angina pectoris.

His literary work includes besides his famous treatise "Diseases of the Heart," of which a fourth edition is shortly to be issued, with the author's revision, by the Oxford University Press; "Symptoms and their Interpretation," and "The Principles of Diagnosis and Treatment in Heart Disease," both of which have been the subject of wide translation and re-issue; a treatise on "Heart Disease in Pregnancy" and one on "Angina Pectoris," which was published last year. He was also the author of contributions to two volumes of "Reports of the St. Andrews Institute," the second of which is reviewed this week in our columns; he delivered the Gibson Memorial Lecture before the University of Edinburgh and the Schorstein Lecture at the London Hospital.

He married in 1887 Frances, daughter of Mr. George Jackson, who survives him.

A TRIBUTE TO SIR JAMES MACKENZIE FROM HIS ST. ANDREWS COLLEAGUES.

Dr. DAVID WATERSTON writes:

"In the deep sense of recent personal loss, it is not easy for his St. Andrews colleagues to pay an adequate tribute to the memory of Sir James Mackenzie, and it is possible only briefly to mention some aspects of his work and his influence there.

"Sir James Mackenzie's work culminated in his foundation of the Institute for Clinical Research at St. Andrews. The reasons which induced him to found the Institute there and the special line of research which he desired the Institute to represent have been fully expounded by himself in various papers and in the reports of the Institute. As a clinical investigator his work began with the observations which he made while in practice in Burnley. His busy consulting and hospital practice in London added to the wealth of his experience, but it was in his work at the Clinical Institute that he summed up and put forth the considered conclusions drawn from the clinical observations made during the course of his life's work.

"The conception of an Institute devoted to clinical investigation was the outcome of his pioneer work as an investigator while a general practitioner. He formulated the fundamental truth that medicine is a special branch of science dealing with a special group of phenomena to which the clinical investigator must apply the methods which are specially suitable for his purpose. Other sciences have their contribution to make to medicine, but they are to be regarded as only ancillary and not replacing the proper methods of clinical investigation into the phenomena of ill-health and disease which afford the material for study. Among other things, it was essential, in his view, to employ the opportunities the general practitioner alone possesses of watching the 'life-history' of ill-health in patients over a long course of years.

"St. Andrews was known to him, was a place of convenient size, and seemed in other respects suitable for launching his great enterprise. After paying some visits to it he decided to give up his appointments and his work in London and to devote his energy and ability to this new field. What it meant to leave London and his work there is not easily estimated. The London Hospital authorities had given him every facility for special hospital work. His position had been recognised as a great consultant, clinician, and teacher. He deeply appreciated the facilities which had been afforded him both at the London Hospital and at the Hampstead Hospital (Mount Vernon). But he realised that he could not in London carry on the work which he felt was fundamentally necessary for the advance of medicine, and after full consideration he decided to abandon this work and to devote himself to founding a Research Institute.

"He came to St. Andrews unknown by name to all but a few of his medical colleagues and began at the cottage hospital a series of clinics in the out-patient department, to which he soon attracted all the practitioners. These clinics rapidly produced the desired effect and aroused in his audience the desire to coöperate in the work which he showed was waiting to be done. With the assistance of generous friends who were deeply interested in his ideas, and with his own financial help, a suitable building was secured and fitted up, and the definite work of the Institute was begun. At a later stage, as the usefulness and value of the work became realised, additional help was given by the Carnegie Trust and by the Medical Research Council.

"Of the work which has been accomplished at the Institute this is not the occasion to write at length, nor is it possible as yet fully to estimate the significance and the far-reaching results of this pioneer movement in medicine. It has already had an influence far wider than a merely local one, and medical thought and medical practice in many countries of the world have received from it direction and guidance. The recent award of the Mickle Fellowship of the University

of Toronto is an illustration of the wide recognition given to his work in St. Andrews. For three years he devoted his whole time and thought to the work of the Institute and to the training of those who worked with him there, and then, satisfied that he had laid down the lines for their work, he gradually withdrew himself from active direction, and gave to the members of the Institute the opportunity of carrying on the work by themselves. At a still later stage his health began to fail, and he decided to winter in a milder climate, but to the very last the welfare of the Institute was foremost in his interests and thought.

"It is not easy for his colleagues to realise fully the extent of the loss they have sustained by his sudden death. His vivid personality and the vigour of his mind had made a deep impression upon them, and the stimulus of coming into contact with him in discussion and debate was of incalculable benefit to them all. They realised the greatness of his genius and his extraordinary insight into medicine, and they had come to look upon him not only with respect and admiration, but with the most sincere affection.

"Great as was the influence of his personality his colleagues feel that the value of his work did not depend upon that element, and will not end with his death. Not only in his work upon the heart, but in the wider field of general medicine, his observations and the principles which he has deduced from them are of permanent and abiding value."

SIDNEY BARWISE, B.Sc. BIRM., M.D. LOND.,
D.P.H. CAMB.

THE sudden death on Jan. 24th of the medical officer of health for Derbyshire came as a shock to his many friends in the public health service. Dr. Barwise was in his sixty-third year, but he had retained the keenness and energy of youth and up to the last gave the impression of having many more years of active life in front of him. His student days were spent in Birmingham where, as a pupil of Dr. Alfred Hill, then medical officer of that city, he acquired a keen interest in chemistry. After holding residential appointments at the Queen's Hospital in Birmingham, Barwise took the D.P.H. at Cambridge in 1889 and became medical officer of health of Blackburn. While there he made a useful report on the smoke nuisance. In 1891 he was appointed, from among 56 applicants, medical officer of health for Derbyshire, a position which he held for nearly 35 years. His intimate knowledge of chemistry and his subsequent experience soon marked him out as an expert in the questions of sewage purification and the prevention of the pollution of rivers. During the gradual change over from the environmental to the domestic aspect of public health, Dr. Barwise's keen intellect enabled him to adapt himself to the new conditions, and through his instrumentality Derbyshire is now regarded as one of the most progressive counties in nursing, maternal care and child welfare, dental treatment, and all matters appertaining to the school medical service. Recent instances of his activities have been campaigns in favour of clean milk and of what is known as the newer knowledge of nutrition. In his last report considerable space was devoted to helio-therapy and helio-hygiene; in the Derbyshire sanatoriums all the various treatments which have been recommended for tuberculosis have been tested. This report also contained an important administrative study of goitre, which has been reprinted, and it will be for others to initiate action on the lines advocated with a view to making "Derbyshire neck" a thing of the past.

The methods which Dr. Barwise adopted in sifting new proposals were thorough, but when once he had made up his mind he took a strong line. As was natural, he occasionally aroused considerable opposition, as in the recent case of the employment of dental dressers. Those who heard Dr. Barwise explain his views on this subject felt that, in his hands at any rate, the scheme was sound and did actually give

results. His opponents in this and other matters would be the first to acknowledge that Dr. Barwise, though keen, was a courteous and fair fighter. In a period of rapid advance in the science and art of public health Dr. Barwise will be remembered as one who was never content with achievement, and was always ready to consider and adopt new measures.

CHARLES MOLESWORTH TUKE, M.R.C.S. ENG.

Dr. Charles Tuke, whose death occurred in London on Jan. 24th, bore a name associated for several generations with the enlightened care of the mentally ailing, but was not an actual descendant of William Tuke, the founder of the York Retreat. His father was Dr. T. Harrington Tuke, for many years proprietor of a private asylum at the Manor House, Chiswick, and Charles Tuke, in coöperation with his brother, the late Thomas Seymour Tuke, for many years carried on the father's work at Chiswick House, to which beautiful place the institution was removed. Charles Tuke was a student at St. George's Hospital, where he held several house appointments before becoming resident clinical assistant at Bethlem Royal Hospital, which, and his family connexions, determined his future outlook. He was an active member of the Medico-Psychological Association and became President of the West London Medico-Chirurgical Society. In his younger days he was a well-known cricketer, for several seasons being a successful bowler in the Middlesex county team.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED JAN. 17TH, 1925.

Notifications.—The following cases of infectious disease were notified during the week, namely—small-pox, 113; scarlet fever, 1910; diphtheria, 1089; enteric fever, 27; pneumonia, 1261; puerperal fever, 47; cerebro-spinal fever, 9; acute poliomyelitis, 6; acute polio-encephalitis, 1; encephalitis lethargica, 31; continued fever, 3; dysentery, 13; ophthalmia neonatorum, 81. There were no cases of cholera, plague, or typhus fever notified during the week. The number of small-pox cases exceeded 100 for the first time for a twelvemonth.

The cases of dysentery were notified, one from the metropolitan borough of Southwark, the others from the following counties: Chester, 1 (Macclesfield); Durham, 1 (Sunderland); Gloucester, 2 (Bristol); Lancaster, 1 (Whiston R.D.); Stafford, 1 (Cheadle R.D.); Surrey, 3 (Woking); Yorks E. Riding, 1 (Kingston-upon-Hull); Yorks W. Riding, 2 (Leeds).

Deaths.—In the aggregate of great towns including London, there were 6 deaths from enteric fever, none from small-pox, 13 from scarlet fever, 49 from diphtheria, 56 from measles; 142 from influenza, as compared with 124, 100, and 83 in the three preceding weeks. In London itself the deaths from diphtheria numbered 12 and from whooping-cough 34.

THE case of *Rex v. Bateman* will be before the Court of Criminal Appeal on Monday next, Feb. 2nd.

ROYAL SANITARY INSTITUTE.—A sessional meeting will be held at 90, Buckingham Palace-road, London, S.W., on Tuesday, Feb. 10th, at 6 P.M., when a discussion will take place on Food and Health, to be opened by Major-General Sir Wilfred Beveridge, followed by Dr. W. M. Willoughby. The chair will be taken at 6 P.M. by Dr. Louis C. Parkes, deputy chairman of the Council.

MANCHESTER'S FILM CRUSADE AGAINST VENEREAL DISEASE.—A campaign to fight venereal disease was begun on Jan. 26th and will be continued until Feb. 14th. By means of a series of cinematographic films, the Manchester Public Health Department will endeavour to draw the attention of the public to the gravity of venereal diseases and the urgent need from the social and individual standpoint for immediate and continued treatment at the free clinics which are provided in the city. Men and women and girls over 15 years and boys over 17 years are invited, and the film displays will be free. Films of a biological character will be shown at meetings for women only. The films will be shown at various public halls in the city and in adjacent townships. Amongst the films which are to be shown are "The End of the Road," "Damaged Goods," "How Life Begins," "The Shadow," and "The Flaw." All the films to be shown have the approval of the Ministry of Health and the Public Health and Watch Committee of the city.

Medical News.

UNIVERSITY OF OXFORD: Scholarships in Natural Science.—Scholarships in Natural Science (for which intending students of medicine are eligible equally with others) are offered for competition as follows: Keble College, examination beginning on March 16th; Merton, Exeter, New, Brasenose, Corpus Christi, and Wadham Colleges examination beginning on March 17th.

The Romanes Lecture for 1925 will be delivered by Sir William Bragg, F.R.S., Hon. Fellow of Trinity College, Cambridge, and Fullerian Professor of Chemistry at the Royal Institution, in the Sheldonian Theatre, on May 20th, at 5.30 P.M., on the Crystallin State.

UNIVERSITY OF LONDON.—A course of eight lectures on the Chemistry of the Internal Secretions will be given by Dr. E. C. Dodds, lecturer in biochemistry and chemical pathologist to the Middlesex Hospital, at Middlesex Hospital Medical School, Cleveland-street, W., at 5 P.M., on Tuesdays and Thursdays, Feb. 3rd, 5th, 10th, 12th, 17th, 19th, 26th, and March 3rd. Attendance at this course is recognised in connexion with the B.Sc. (Honours) Degree in Physiology. A course of four lectures on the Medullary Centres will be given by Dr. J. M. Duncan Scott at St. Bartholomew's Hospital Medical School, 6, Giltspur-street, E.C., at 5 P.M., on Wednesdays, Feb. 11th, 18th, 25th, and March 4th. Admission to both courses of lectures is free.

SOCIETY OF APOTHECARIES OF LONDON.—At examinations held recently the following candidates passed in the subjects indicated:—

Surgery.—A. J. Dowek, Manchester; T. McD. Kellough and J. Maingard, Guy's Hosp.; E. J. P. McDowell, St. Thomas's Hosp.; A. Mishriky (Sect. II.), St. Mary's Hosp.; B. L. Steele, Univ. Coll. Hosp.; and C. C. Taffs, St. Thomas's Hosp.

Medicine.—W. Bentley, Birmingham; C. V. Brown (Sect. I.), Guy's Hosp.; N. E. Challenger, McGill; L. Freeman, St. Thomas's Hosp.; E. F. Hottinger, St. Mary's Hosp.; R. C. Pratt (Sect. I.), Birmingham; C. W. Warne, Guy's Hosp.; and D. Winstanley, Liverpool.

Forensic Medicine.—N. E. Challenger, McGill; E. F. Hottinger and W. Johnson, St. Mary's Hosp.; W. Irving Pierce, Boston, U.S.A.; R. J. Rutherford, Durham; and H. Winstanley, Liverpool.

Midwifery.—M. R. Burke, St. George's Hosp.; F. Carroll, St. Mary's Hosp.; C. E. Hagenbach, St. George's Hosp.; E. F. Hottinger, St. Mary's Hosp.; A. J. Moody, St. Bart's Hosp.; K. E. R. Robertson, St. Mary's Hosp.; and H. Winstanley, Liverpool.

The Diploma of the Society was granted to the following candidates entitling them to practise medicine, surgery, and midwifery: A. J. Dowek, L. Freeman, E. F. Hottinger, E. J. P. McDowell, A. J. Moody, C. C. Taffs, and C. W. Warne.

EDINBURGH UNIVERSITY ALUMNI ASSOCIATION.—A meeting of the Alumni Association of Edinburgh University was held on Jan. 23rd in the McEwan Hall, at which the Earl of Balfour, K.G., Chancellor of the University, delivered an address. Sir Harold Stiles, the founder of the movement a year ago, took the chair, and in opening the meeting stated that having seen the great benefits which accrued from similar institutions in America, he had suggested that an Alumni Association be instituted in Edinburgh University. The object was to try to produce a relation between Alumni of the University in all parts of the Empire, and to do everything to promote the interests of their Alma Mater. The movement had taken root, 842 graduates had joined, and £1075 had been subscribed. That very morning he had received from one of his old house surgeons, Dr. Charles Cooper of San Francisco, a gift of £1000 to be used in giving practical advice to young graduates in research. Lord Balfour commenced by saying that he rejoiced in having an opportunity of addressing representatives of the University with which he was so closely connected on a subject which he was convinced was going to have in this country, as it has already had in America, a great and growing success. The subject touched a side of University life too often forgotten; the individual graduate was too apt to consider a University as a mechanism for imparting a certain amount of learning. This, doubtless, he said, was its main and primary object, but a man who leaves a university having only obtained a modicum of intellectual education and a certain equipment for the struggle of life is a man greatly to be pitied; a university gave a man much more than this. Anybody who had been through a university, and who had tried to measure all he has gained from its instructions and its life would find that after all it was the human intercourse which accompanied it, patriotism and traditions, which all combined to form a bond of union. Another side of the question was that of money. For this he felt strongly, that large sums should not be asked of any member of the

Association. The sum asked was deliberately kept within the means of those whose incomes were small, but it was to be hoped that the obligatory sum would in many cases be exceeded, especially by those Alumni whose success was due to their past training. The cost of medical teaching had greatly increased, and the cost of research had been added to it in every university worth the name. Literature, mathematics, history, philosophy, and theology given a suitable building, good lecture rooms, good lecturers, and willing students might be taught at no great expense, but in the case of medicine and experimental science the cost of teaching was growing—it could not be done on the cheap. Debts of gratitude, he continued, were due to citizens of Edinburgh for the help they had afforded, also to such bodies as the Rockefeller Trust. Students' fees and endowments from Government and local authorities, however, were not sufficient; what was required was that past members of the University should subscribe according to their means, and that the money collected be turned to the best account.

HUNTERIAN SOCIETY.—The annual dinner will be held at the Hotel Victoria, Northumberland-avenue, on Feb. 12th at 7.30 P.M. Fellows are asked to notify the hon. secretaries, at 94, Harley-street, W. 1, as soon as possible the number of guests they intend to bring.

RONTGEN SOCIETY.—A meeting will be held on Feb. 3rd at 8.15 P.M. in the British Institute of Radiology, 32, Welbeck-street, London, W., when a paper on Constant Voltage High Tension Generators will be read by Major C. E. S. Phillips and one on Some Further Aspects of the Theory and Operation of Potter-Bucky Diaphragms, by Mr. C. H. Holbeach, who will also give a demonstration of the new C.D.X. dental X ray equipment.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—On Monday, Feb. 2nd, Mr. Arthur Giles will lecture for the Fellowship of Medicine on the Operative Treatment of Uterine Displacements. The lecture will be delivered in the West Lecture Hall of the Royal Society of Medicine at 5.30 P.M. During the month of February the following courses will be held: A three weeks' combined course in Diseases of Children, arranged by the Paddington Green Hospital, Victoria Hospital, and the Children's Clinic; a four weeks' course in Dermatology at the St. John's Hospital for Diseases of the Skin; a month's course in Venereal Diseases at the London Lock Hospital, and as this course is not held unless eight entries are received early application is desirable; and eight clinical demonstrations (twice a week) spreading over a month at the School of Tropical Medicine. For the last fortnight of February a course will be held in General Medicine and Surgery and the Special Departments, at the North-East London Post-Graduate College (Prince of Wales's Hospital, Tottenham, N.), for which early application should be made. In March there will be courses in Diseases of the Chest, Brompton Hospital; Medicine, Surgery, and Gynaecology, at the Royal Waterloo Hospital; Gynaecology, at the Chelsea Hospital for Women; Infectious Fevers, at the North-Eastern Hospital, Tottenham; and an intensive course dealing with Medicine, Surgery, and the Various Specialties, at the Royal Northern Hospital, with which will be associated the Royal Chest Hospital. Copies of the syllabus of the above-mentioned courses, together with the Fellowship Bulletin, may be had on application to the Secretary at 1, Wimpole-street, W. 1.
